Effect of laser treatment for dry age related macular degeneration on foveolar choroidal haemodynamics

EXTENDED REPORT

Aim: Previous studies have suggested that laser photocoagulation therapy is associated with the resolution of drusen in some age related macular degeneration (AMD) patients. The main aim of the study was to determine whether low intensity laser treatment applied according to the Complications of AMD Prevention Trial (CAPT) protocol produces changes in the choroidal circulation that may help explain the mechanism leading to the resolution of drusen material.

Methods: This ancillary study included 30 CAPT patients with bilateral drusen that were treated and followed at the University of Pennsylvania. Laser Doppler flowmetry was used to measure relative choroidal blood velocity (Chvel), volume (Chvol), and flow (Chflow) in the centre of the fovea. Measurements were obtained through a dilated pupil in both eyes of each patient at the initial CAPT visit before laser treatment was applied in one eye. Measurements were repeated in both eyes of each subject three months later. Analysis of laser Doppler measurements was performed in a masked fashion.

Results: In comparison to baseline, no significant differences in Chvel, Chvol, or Chflow were observed three months following the application of low intensity laser according to the CAPT protocol in the untreated and treated eyes. In comparison to the untreated eyes, no significant differences were detected in the treated eyes. Based on the variability of flow measurements in the untreated eyes, the authors estimated an 85% power to detect a 15% change in relative blood flow.

Conclusions: The results suggest that large alterations in choroidal blood flow do not occur at three months after low intensity laser therapy following the CAPT protocol.

METHODS

The study population included 30 AMD patients (17 female and 13 male) with bilateral drusen who were enrolled in the CAPT at the Scheie Eye Institute. Eligibility was determined according to the CAPT entrance criteria. Mean age was 71 (standard deviation, SD 6) years (range 55 to 82 years). All eyes included in the study had deep anterior chambers and pupillary dilatation greater than 5 mm. All subjects agreed to participate in our study by signing a consent form approved by our institutional review board.

Information about systemic and ocular medications as well as medical and ocular history was obtained from each patient. Eleven patients had a history of hypertension and 10 of them were on systemic therapy. Six patients were on antilipaemic medication. Nineteen were taking multivitamins. One patient had had cataract surgery before the study.

Bilateral pupillary dilatation was achieved with tropicamide 1% and phenylephrine hydrochloride 2.5%. Measurements of relative foveolar choroidal blood velocity (Chvel), volume (Chvol), and flow (Chflow) were obtained using laser Doppler flowmetry (Oculix instrument) in both eyes of each subject. Chvel represented the speed of moving blood cells whereas Chvol corresponded to the amount of blood present at the measurement site. Chflow was calculated by the instrument from Chvel and Chvol. Descriptions of the method have been previously reported. A 20 μW diode laser beam (670 nm) with a diameter of 200 μm was delivered through a fundus camera (Model TRC, Topcon, Tokyo, Japan).

Subjects were asked to fixate on the probing laser beam. A 30° area of the posterior retina was illuminated at a wavelength of 570 μm with a retinal irradiance of approximately 0.03 mW/cm² in order to observe the position of the laser beam on the foveola. Proper fixation was confirmed by direct visualisation of the foveola through the fundus camera. This method allows for determinations of choriocapillary flow as discussed by Riva et al. All measurements were performed with the subjects seated in a darkened room.

Abbreviations: AMD, age related macular degeneration; CAPT, Complications of AMD Prevention Trial; CNVPT, Choroidal Neovascularisation Prevention Trial.
In both eyes of each patient, three separate 20–30 second measurements of the choroidal circulation were obtained. Following baseline determinations, patients were treated in one eye according to the CAPT protocol. In one eye determined at random, 60 light intensity, 100 μm diameter laser photocoagulation burns were applied in a circle at a distance of 1500–2500 μm from the centre of the foveola. Three months after treatment, choroidal blood flow determinations were repeated in both eyes.

A trained observer masked to the eye treated, timing of measurements, as well as all other patient’s attributes, analysed the data using a NeXT computer (NeXT Computer Inc, Redwood City, CA, USA) with software specifically developed for the analysis of Doppler signals from ocular tissues (NeXT Software Inc).

The masked observer selected segments of the recordings that showed stable circulatory parameters, to avoid unstable blood flow readings produced by disturbances such as eye and head motion, poor fixation, and blinking. Data obtained from the three separate recordings were averaged.

Heart rate, brachial artery systolic (BP s) and diastolic blood pressure (BP d), and intraocular pressure (IOP) measurements were obtained upon completion of laser Doppler flowmetry measurements. Mean blood pressure (BP m) was calculated using the following standard formula:

\[ BP_m = \frac{BP_s + 1/3 BP_d}{2} \]

The perfusion pressure (PP) was calculated according to the formula:

\[ PP = \frac{2}{3} BP_m - IOP \]

Two tailed, paired Student’s t tests were employed for the statistical analysis, and p values of less than 0.05 were considered statistically significant.

**RESULTS**

No statistically significant changes from baseline were observed in the treated or the untreated eyes at 3 months. In comparison to the untreated eyes, there were also no statistically significant differences in the changes in time in the treated eyes.

Figure 1 shows Ch vel measurements obtained at baseline and 3 months in the untreated and treated eyes for each subject. No significant difference in mean Ch vel was observed between baseline (0.41 (SD 0.07) arbitrary units (AU); table 1) and 3 month measurements (0.42 (SD 0.09) AU; paired Student’s t test, p = 0.5) in the untreated eyes. Also no significant difference in mean Ch vel was observed between baseline (0.42 (SD 0.07) AU; table 2) and 3 month measurements (0.40 (SD 0.07) AU; paired Student’s t test, p = 0.4) in the treated eyes.

Figure 2 shows Ch vol measurements at baseline and 3 months in the untreated and treated eyes for each subject. No significant difference in mean Ch vol was observed between baseline (0.21 (SD 0.06) AU; table 1) and 3 month measurements (0.21 (SD 0.07) AU; paired Student’s t test, p = 1.0) in the untreated eyes. Also, no significant difference in mean Ch vol was observed between baseline (0.19 (SD 0.06) AU; table 2) and 3 month measurements (0.20 (SD 0.07) AU; paired Student’s t test, p = 0.4) in the treated eyes.

Figure 3 shows for each subject Ch flow measurements at baseline and 3 months in the untreated and treated eyes. No significant difference in mean Ch flow was observed between baseline (7.3 (SD 2.0) AU; table 1) and 3 month measurements (7.3 (SD 2.5) AU; paired Student’s t test, p = 0.8) in the untreated eyes. Also no significant difference in mean Ch flow was observed between baseline (6.8 (SD 1.8) AU; table 2) and 3 months measurements (7.0 (SD 2.3) AU; paired Student’s t test, p = 0.5) in the treated eyes.

Figure 4 shows for each subject a comparison of the changes in Ch flow from baseline observed at 3 months in the untreated and treated eyes. No statistically significant difference was observed between the mean changes in Ch flow observed in the untreated and treated eyes (paired Student’s t test; p = 0.6).

There were no significant correlations between blood pressure (systolic, diastolic, and mean), perfusion pressure, or heart rate changes and changes in Ch vel, Ch vol, or Ch flow.

Based on the variability of flow measurements at three months in the untreated eyes, we estimated that we have an 85% power to detect a 15% change in relative blood flow.

**DISCUSSION**

A number of studies have suggested that laser photocoagulation treatment can reduce the area of drusen in patients with AMD. Although the exact mechanism by which laser treatment causes drusen resolution is not known, it is...
possible that the choroidal circulation may play a role in this phenomenon. The choroidal circulation is the only vascular supply that nourishes the outer retina. Removal of drusen material and metabolic waste products from the retinal pigment epithelial (RPE) Bruch’s complex most probably occurs through this circulatory bed.

Several studies have reported evidence suggesting that choroidal haemodynamic abnormalities are present in AMD. In a prospective study, Holz et al. found that patients with delayed choroidal perfusion on fluorescein angiography had a higher risk of developing new AMD lesions. Friedman et al. found a significantly higher coefficient of scleral rigidity in AMD patients—a finding that may be associated with increased scleral rigidity that could interfere with venous outflow. Our group has reported, using laser Doppler flowmetry, that choroidal blood flow decreases with age, and that this decrease is more marked in patients with non-exudative AMD than in age matched controls. Ciulla et al. have described delayed and heterogeneous filling of the choroid, particularly in the perifoveal region—a finding that suggests again an abnormality of the choroidal circulation.

Such a reduction in the circulation of the choroid—the only vascular bed that supplies the outer retina—could be related to the accumulation of drusen material in the RPE Bruch’s membrane complex. Potentially, an increase in blood flow could lead to a faster removal of metabolic waste products in the RPE Bruch’s membrane complex.

To investigate whether choroidal circulatory changes are associated with the reabsorption of drusen material following laser treatment, we have assessed the choroidal circulation just before and 3 months after low intensity laser treatment.

Our results, however, do not show any statistically significant

effect of laser treatment on the choroidal circulation 3 months after treatment. Changes in choroidal blood flow may occur later and we are currently collecting circulatory data two years after the initial low intensity laser treatment to test this hypothesis.

There is evidence to suggest that most of the resolution of drusen following laser treatment may occur later than 3 months. Figueroa et al. performed a study in which laser was applied directly onto temporal drusen and reported a mean time of drusen disappearance of 2 months. However, the investigators noted that drusen further away from the site of treatment resolved more slowly, with a mean time of about 10 months. These results suggest that directly treated laser applications resolved more slowly, with a mean time of drusen resolution of 2 months. However, the initial CAPT low intensity laser treatment is not applied directly onto drusen, it is likely that the resolution of drusen takes more than 3 months. As the CAPT is still ongoing, information about the timing and extent of this resolution of drusen material will not be available until the end of the study in 2006.

Another explanation for the lack of significant change in circulatory parameters at three months may be that in our study we are assessing the choroidal circulation in the centre of the fovea, an area that is not directly treated with laser spots in the CAPT protocol. Because we did not find any significant effect of laser treatment on the choroidal circulation at 3 months after treatment, we have calculated the statistical power that we have to detect circulatory changes. Based on the variability of flow measurements at 3 months in the untreated eyes, we estimated that we have an 85% power to detect a 15% change in relative blood flow.

We are currently investigating the changes that occur in the choroidal circulation 2 years after low intensity laser treatment to assess whether such changes may occur after 3 months. Because the CAPT study is being carried out in a masked fashion, we do not have data on which specific eyes have shown resolution of drusen. When this information is released in 2006, we will be able to test whether patients who show resolution of drusen after treatment have choroidal circulatory changes that are different from those eyes that do not show resolution.
