Effect of preoperative fusidic acid on the normal eyelid and conjunctival bacterial flora

PETER B TAYLOR, KHALID F TABBARA, AND EILEEN M BURD

From the Department of Ophthalmology, College of Medicine, King Saud University and the King Khaled Eye Specialist Hospital, Riyadh, Saudi Arabia

SUMMARY A randomised trial comparing the topical application of 1% fusidic acid with 0·3% gentamicin solution in the reduction of the normal preoperative lid and conjunctival microbial flora was performed. Forty patients awaiting cataract surgery were randomly divided into two groups consisting of 20 patients each. The first group received a 1% microcrystalline suspension of fusidic acid, the second 0·3% gentamicin to the preoperative eye every two hours between 0600 and 2400 daily for 48 hours preoperatively. Cultures were obtained from both the lid margins and the conjunctival sac of both groups prior to antibiotic therapy and again in the operating theatre before surgery. Microbiological identification and colony counts were performed by standard laboratory methods. Staphylococcus epidermidis was the commonest micro-organism isolated. Statistical analysis revealed no significant differences in the ability of a 1% microcrystalline suspension of fusidic acid and 0·3% gentamicin in eliminating or reducing the normal preoperative conjunctival or lid flora.

Postoperative infections, especially endophthalmitis, are serious complications of intraocular surgery. The aetiological agents of postoperative infections are often introduced intraocularly from the patient’s own normal eyelid and/or conjunctival bacterial flora during surgical manipulation.1 2 To minimise the risk of postoperative infections prophylactic topical antimicrobial therapy is usually administered prior to intraocular surgery.

Bactericidal antibiotics are usually preferred for use in prophylaxis. To ensure protection from both Gram-positive and Gram-negative micro-organisms a broad-spectrum antibiotic such as gentamicin or erythromycin, or a combination of bacitracin and polymyxin, are frequently used in prophylaxis. The choice of a topical prophylactic antibiotic should be based on its efficacy against the causative agent, its low toxicity, low risk of systemic sensitisation, and reasonable cost.

It has been well established that Gram-positive organisms, particularly staphylococci, are the main constituents of the normal ocular flora and are also the predominant cause of postoperative infections.3 Fusidic acid (Fucidin) is a steroidal antibiotic isolated from the fermentation products of the fungus Fusidium coccineum. It is chemically related to cephalosporin P, but it has no cross-reactivity with any other commonly used antibiotics. Fusidic acid was introduced in Europe in 1962 and has been effective against a wide range of Gram-positive organisms, with low activity against Gram-negative organisms and fungi, in the concentration range of the relatively low blood levels acquired with the recommended systemic doses.4 It has the greatest antistaphyloccocal (both β-lactamase positive and negative) activity of any antimicrobial agent currently available.4 5 6

The topical ophthalmic fusidic acid preparation (Fucithalmic) would be expected to be effective against a wide range of Gram-positive organisms4 7 and some Gram-negative organisms1 4 8 in view of its minimal inhibitory and minimal bactericidal concentrations. Fusidic acid can penetrate avascular tissue even in large collections of pus.9 10 The topical preparation has little or no epithelial toxicity and covers organisms such as Streptococcus spp. that are missed by other traditionally used prophylactic aminoglycosides. The following trial was undertaken to compare the efficacy of Fucithalmic with gentamicin in the preoperative prophylactic reduction of ocular flora.

Effect of preoperative fusidic acid on the normal eyelid and conjunctival bacterial flora

Material and methods

To evaluate the potential use of fusidic acid for prophylaxis prior to intraocular surgery 40 consecutive patients awaiting cataract surgery were randomly divided into two groups of 20 patients each. The first group received topical 1% fusidic acid microcrystalline suspension (Fusithricid) and the second group received 0.3% gentamicin ophthalmic solution in the preoperative eye. The drops were administered one drop every two hours beginning at 0600 until 2400 for 48 hours prior to surgery, the last dose being given at midnight the night before surgery. Phisohex face scrubs were given the evening before and again on the morning of surgery as part of the standard preoperative procedure.

To assess the antimicrobial effectiveness of the prophylactic medication cultures for bacteriological evaluation were taken before beginning prophylactic treatment and again in the operating room just prior to preparation for surgery. Cultures of the eyelids were obtained by rubbing a sterile cotton-tipped swab moistened in trypticase soy broth from the canthal eyelid margin of the lower eyelid to the temporal margin and back again. Conjunctival cultures were taken in a similar manner while pulling down on the lower eyelid with care to avoid the lid margins and lashes. The specimens were streaked on 5% sheep blood agar and chocolate agar plates. Cultures were incubated at 37°C and observed at 24 and 48 hours.

The number of bacterial colonies growing were counted and quantitated with findings of less than 50 colonies graded as scant to light growth, 50 to 149 as moderate, and 150 or more as heavy growth. The bacteria were identified by standard bacteriological techniques. Antimicrobial sensitivity testing was done by the modified Kirby-Bauer disc diffusion method using Mueller Hinton agar. Statistical analysis of the data was performed by the Wilcoxon signed rank test and the binominal test for proportions to evaluate the significance of the results.

Results

**CONJUNCTIVA**

The cultures of the conjunctivae from 22 of the 40 patients (55%) revealed moderate pretreatment growth of *Staphylococcus epidermidis*; six of 22 (27%) had concomitant growth of other organisms. Of the mixed growth cultures, two included light growth of *Corynebacterium* species, one with light growth of a streptococcus (alpha-hemolytic), one with light to moderate growth of both *Morganella morganii* and *Corynebacterium* species, one with light growth of *Staphylococcus aureus*, and one had scant growth of *Citrobacter diversus*. Of the remaining 18 patients one had only light growth of *Streptococcus acidominimus*, one grew mixed scant to light *Str. morbillorum* and *Corynebacterium* species; 16 of the 40 patients (40%) showed no growth prior to initiation of therapy.

Following treatment only one eye in each of the antibiotic treatment groups showed growth of *Staphylococcus epidermidis*. In both of these cases the organism was resistant to the antibiotic used for that eye. In the fusidic-acid-treated eyes the quantity of growth decreased from a pretreatment of light to a post-treatment of scant growth. In the gentamicin-treated eye no organisms were found before treatment; but moderate growth of *Staph. epidermidis* was found after treatment. The other organisms (*Corynebacterium* and *M. morganii*) found before treatment in the patients using fusidic acid were completely eliminated, as were the organisms (*Streptococcus* species, *Staph. aureus*, and *Citrobacter diversus*) in the gentamicin-treated patients.

In one gentamicin-treated patient, however, cultures after treatment revealed 94 colonies of *Micrococcus* species resistant to gentamicin which were isolated from the eye of a pretreatment-negative patient (Table 1).

*Other includes cultures with more than one organism isolated.

**LID MARGINS**

The eyelids of all patients showed bacterial growth before treatment. Of the 40 eyes 37 (93%) revealed moderate to heavy growth of *Staphylococcus epidermidis*. Of those with positive cultures for *Staph. epidermidis* 9 (24%) had concomitant growth of other organisms. Of those eyelids giving a mixed growth one gave a moderate growth of *M. morganii* and *Corynebacterium* species, one scant growth of *Bacillus* species, one scant to light growth of *Klebsiella pneumoniae* and *Corynebacterium* species, one moderate growth of *Corynebacterium* species, one moderate growth of *C. diversus*, one scant growth of *Str. morbillorum*, *Enterobacter agglomerans*, and heavy growth of *Corynebacterium* species, one moderate growth of *Moraxella* species,
and two eyes gave scant and heavy growth of Staph. aureus. The lids of three of the 40 eyes (7%) gave pure growths of other organisms, two with heavy growth of Staph. aureus and one with moderate to heavy mixed growth of Staph. epidermidis and Corynebacterium species.

Post-treatment lid margin cultures of those with pretreatment Staph. epidermidis showed complete elimination (no growth) in 10 of the 18 (55%) patients receiving fusidic acid and in 15 of the 19 (79%) receiving gentamicin. Of the remainder of those with post-treatment Staph. epidermidis, only 14 of the 37 (38%) showed a significant reduction in growth quantity for the two different antibiotics (Table 2).

All other organisms found in pretreatment cultures were completely eliminated in cultures taken after treatment. However, in one patient receiving gentamicin a Micrococcus species resistant to gentamicin was isolated that was not present in pretreatment cultures.

Statistical analysis comparing pretreatment and post-treatment counts using Staphylococcus species growth as a sample showed significant reduction in bacterial flora for both conjunctiva and lid margins whether treated by fusidic acid or gentamicin (Tables 1 and 2) (conjunctiva: fusidic acid, p=0.0005; gentamicin, p=0.0117; lid margin: fusidic acid, p=0.0001; gentamicin, p=0.0007). No significant differences (eyelids, p=0.478; conjunctiva, p=0.97) were found when comparing post-treatment colony counts of fusidic-acid-treated versus gentamicin-treated eyes.

**SUMMARY OF RESULTS**

In the present study fusidic acid either eliminated or reduced the colonies of Staph. epidermidis present in all but one of the eyes studied. The one case in which there was an increase in the number of Staph. epidermidis colonies along the lid margins involved a resistant strain. Resistance of Staph. epidermidis was found in 10-5% of gentamicin-treated eyes and 28% of Fucithalmic-treated eyes. One lid margin was found to have heavy growth of resistant Staph. aureus organisms that were completely eliminated by topical Fucithalmic. Other bacteria, including α-haemolytic streptococcus, Bacillus spp, Klebsiella pneumoniae, and Morganella morganii which demonstrated resistance in vitro were eliminated from the eyelids and conjunctiva by Fucithalmic. Resistance testing in vitro is based on projected serum levels achieved by systemic antibiotic administration and frequently does not correlate with susceptibility of the organism to topically applied drugs. However, such testing provides useful information on the antibiotic to which the organism is most sensitive. Corynebacterium spp. were also eliminated, though susceptibility testing in vitro was not performed.

**Discussion**

The choice of antibiotic to be used for prevention of postsurgical infections should be based on knowledge of the bacteria usually involved and their general patterns of susceptibility to antibiotics. This knowledge is difficult for any one institution to have because of the relatively few cases encountered; we therefore depend on reports of retrospective studies for such information. Many of the early series reporting postoperative ocular infections did not mention the causative organisms or implicated organisms from improperly sterilised surgical instruments, contaminated solutions, or bacteria from skin or nasal mucosa of surgeon or operating room staff. With improvements in sterile technique, sterilisation of surgical instruments, and strict quality control of solutions and medications, the normal ocular flora have been implicated as the source of postoperative infection in most cases and bacteriophage typing of strains has confirmed this suspicion in one study.

Antibiotics used topically as prophylaxis before
intracocular surgery do not always completely eradicate the indigenous eyelid and conjunctival flora. However, a review of the literature clearly shows that the incidence of postsurgical endophthalmitis was markedly reduced from an average of 1-3% (range, 0.44% to 3.16%) in patients not given prophylactic antibiotics, to an average of 0.335% (range, 0.00% to 0.57%) in patients who did receive prophylactic antibiotics.

The organisms most commonly recovered in cases of postsurgical endophthalmitis include primarily Staph. aureus and Staph. epidermidis. Streptococcus spp., Proteus spp., and Pseudomonas spp. are also commonly seen, although less frequently.

Studies of the efficacy of topical antibiotics in reducing normal ocular bacterial flora have shown that antibiotics vary widely in their ability to reduce or eliminate the normal ocular flora. Although various dosage schedules were used, the superiority of gentamicin 0.3% solution over the following other agents has been clearly demonstrated: chloramphenicol 0.5% solution, sulphacetamide 30% solution, sulphamethiazole 4% solution, bacitracin 1%-neomycin 0.5% solution; neomycin-polymyxin-B-gramicidin solution; rifocetin sulphate 0.5%-polymyxin B 0.25% solution; oxytetracycline chloride 3%-polymyxin B 0.1% ointment; soframycin 0.5% solution; and sodium sulphate 10% solution. In addition, gentamicin 0.3% ointment was as effective as gentamicin 0.3% solution in one study. Gentamicin is an antibiotic whose antibacterial spectrum includes most normal ocular flora, particularly staphylococci.

The present study showed that fusidic acid 1% microcrystalline suspension was as effective as gentamicin in reducing or eliminating Staph. epidermidis present on the lid margin or in the conjunctival fornix of presurgical cataract patients when administered every two hours from 0600 to 2400 for 48 hours prior to surgery. Fusidic acid applied topically penetrates the cornea well (Taylor and colleagues, unpublished data) and is bactericidal in concentrations close to the minimal inhibitory concentration. When topically applied, this microcrystalline suspension of fusidic acid is effective against most Gram-positive bacteria such as Streptococcus spp. which can be missed by more traditional preoperative aminoglycoside therapy. This antibiotic may provide another alternative in preoperative prophylactic antimicrobial therapy.

The topical fusidic acid 1% viscodrops were kindly supplied by Leo Pharmaceuticals Ltd, Denmark.

We thank Robert L Phillips, PhD, and William Greer, PhD, of King Faisal Specialist Hospital and Research Centre for the help with statistical analysis of the data.
