Although simple excision has been successful in some cases, recurrences have been reported in others. The latter authors recommend primary keractomy with insertion of a lamellar graft to lessen the risk of recurrence and provide a better cosmetic result.

Fundus albipunctatus-like lesions in juvenile retinoschisis

Mary J van Schooneveld, Yozo Miyake

Juvenile retinoschisis (XRS) is an X linked vitreoretinopathy characterised mainly by typical maculopathy – namely, foveal schisis. However, the ophthalmoscopic findings may be heterogeneous, varying from a rather subtle cystic maculopathy to what may resemble an old and extensive chorioretinitis. Apart from the maculopathy and peripheral retinoschisis, glistening golden peripheral areas sometimes resembling the Mizuo phenomenon, dendriform lesions, neovascularisation (peripheral and of the optic disc), pigment clumping, dragging of the optic disc, and pseudopapillitis may all be encountered in this condition. In 1981 Boisdequin et al described another peculiar fundus finding in four patients with XRS (including two brothers): a fundus albipunctatus-like aspect. In this paper we describe two other patients with this uncommon fundus appearance to focus attention once more on this manifestation of juvenile retinoschisis and to facilitate its recognition.

Case reports

CASE 1
A 10-year-old Japanese boy was diagnosed as having XRS at the age of 11 months. His maternal grandfather was also known to have this condition.

Visual acuity was 20/200 right eye with S+4.5=C+1×55° and 20/100 left eye with S+3=C+1.25×110°. Both fundi showed the typical star-shaped configuration in the macula and peripheral retinoschisis inferiorly. Furthermore multiple small white flecks were scattered in the temporal posterior pole (Fig 1A and 1B). These bilateral white flecks seemed to be located in the retina and not in the pigment epithelium. The Ganzfeld electroretinogram (ERG) showed markedly reduced scotopic (rod) responses (30–50% of normal value) and even more reduced photopic (cone) responses (20–25% of the normal value) and a negative-type ERG with a single bright flash stimulus. The oscillatory potentials were absent (Fig 2).

Visual fields showed bilateral superior loss corresponding to the schisis areas. There were no complaints of night blindness. In the 62-year-old grandfather the small flecks were absent.

Figure 1A Posterior pole in the right eye of case 1 showing cystic maculopathy and fundus albipunctatus-like lesions.
maculopathy, but no pattern corresponding to the albipunctatus-like flecks (Fig 3B). The ERG was negative with almost absent b-waves and the EOG had a L/D ratio of only 1/16 and 1/08 respectively. Visual fields disclosed superior defects caused by peripheral schisis. Colour vision measured with the 28 hue test was almost normal (some minor mistakes), but of the Ishihara test only 12 plates (including the test plate) were correctly recognised. Subjectively there was no night blindness.

During the 4-5 years of follow up visual acuity remained stable at 20/60 right eye and 20/200 left eye, both with S+4.5.

Comment
In both patients the cystic maculopathy, the peripheral retinoschisis, and the negative configuration of the ERG are characteristic for juvenile retinoschisis. In addition, the maternal grandfather of case 1 was known to have this condition. However, multiple small white flecks were associated with these findings. These small punctate flecks are strongly reminiscent of fundus albipunctatus, including the typical radial orientation relative to the fovea in the first patient (Fig 1A). Fundus albipunctatus is a stationary congenital night blindness disorder characterised by typical white punctate fundus lesions and an abnormal slow regeneration of visual pigment. Although the visual function is stationary, the appearance and number of dots may change over time. 1 Visual acuity should be normal or near normal. Differentiation from retinitis punctata albescens, a condition belonging to the group of tapetoretinal dystrophies, may occasionally be difficult and is made mainly by the progressive character and visual field loss. 

Recently, fundus albipunctatus in combination with cone dystrophy was described by Miyake et al.4 These patients were clearly different from the two patients described in this report, in that the first had progressive loss of central vision starting in adulthood (visual acuity having been normal before), bull's eye maculopathy, no peripheral retinoschisis, and severely reduced photopic ERGs but no negative type ERG.

With fluorescein angiography our second patient also showed a bull's eye maculopathy, which is not typical for XRS, but also is not contradictory. In early stages of XRS, subtle or no fluorangiographic abnormalities in the macular area are seen, but in later stages all kind of transmission defects of the retinal pigment epithelium may be encountered. The albipunctatus flecks could not be traced down in the angiogram, which corresponds to their supposed localisation in the superficial retina.

In most cases of XRS the EOG is normal or moderately reduced, while in our second patient the EOG showed hardly any light increase. However, very abnormal or even flat type EOGs also occur in XRS. 1 As widespread window defects of the retinal pigment epithelium can be seen on the fluorescein angiogram, the pathological EOG in this patient is explicable. Boisdequin et al do not mention EOG results in their four patients, and so we do not know for the

CASE 2
A 13-year-old white male had no maternal relatives with known XRS and genealogical studies revealed no link with other XRS patients. He was seen by an ophthalmologist at the age of 1 year because of a convergent squint of the left eye. Occlusion was not tolerated. The squint was operated on and at the age of 7 low visual acuity was noted: 20/60 right eye and 20/200 left eye.

He was first seen at the department of ophthalmogenetics at the age of 8. His fundi showed impressive cystic maculopathy with bilateral peripheral inferior retinoschisis with obliterated vessels in the right eye and a fibrotic sea fan with some exudates and haemorrhages in the left eye. Both posterior poles showed numerous small white flecks (Fig 3A). Fluorescein angiography showed transmission defects in the pigment epithelium creating a bull's eye
moment whether XRS with fundus albipunctatus-like flecks is associated with an extra low L/D ratio of the EOG.

To our knowledge the fundus albipunctatus-like aspect in XRS has not yet been described, apart from in the paper by Boisdequin et al. In four patients out of nine with XRS described by Boisdequin et al, the white dots were thought to belong to an early stage of the evolution of the maculopathy where the dots represent ‘piilis’ (little strands in the superficial retina) comparable with those in acquired retinoschisis. (The photograph on page 58 in their article is similar to the appearance in our patients.)

Amorphous extracellular material consisting of fine filaments with a specific periodicity of 4 to 5 nm has been described as a pathological feature of XRS. These filaments are supposed to be the product of defective Müller cells.

It is conceivable that the fundus albipunctatus-like flecks in XRS also represent accumulations of this kind of amorphous material. However, there are two inconsistencies in this theory: (1) why is the fundus albipunctatus-like appearance so rarely noted while the deposition of abnormal amorphous material is a regular event in XRS?; (2) the localisation of the punctate white flecks – that is, around the macular area, is not an area in which schisis usually develops.

The first inconsistency could be explained by the assumption that the albipunctatus-like flecks are a transient phenomenon (such as Boisdequin et al propose) occurring only in small children. Our two patients were very young, as were three patients of Boisdequin et al, including two brothers. One of Boisdequin et al’s patients was about 40 years old, but this patient lacked a family history, the typical star-shaped maculopathy, and peripheral retinoschisis, while no electroretinography was performed.

For the second inconsistency we have no suitable explanation.

It is likely that the punctate lesions in XRS have often passed unnoticed. In the article by Greven et al the picture of their patient 4 (21 months old) clearly shows the punctations, but they are not mentioned in the text. On the other hand, when the albipunctatus-like aspect in a particular male patient is noted, but not recognised as a possible manifestation of XRS, diagnostic confusion might ensue. Therefore we wish to report this symptom of XRS. To understand its nature and origin, future observations, both clinical and histopathological, will be important.

M-JVS thanks Professor I N Went for his support and critical comments.

Fundus albipunctatus-like lesions in juvenile retinoschisis.
