LETTERS TO THE EDITOR

Benign flea retina

EDITOR,—We report a case of flecked retinal dystrophy in a child of mixed Australian aboriginal and white descent. Both fundi showed widespread discrete yellow-white fleck lesions at the level of the retinal pigment epithelium, extending to the far periphery but sparing the macular region. Visual acuity was normal and the electroretinogram showed no abnormality. To our knowledge no other family members are affected, and there is no history of consanguinity between the parents. The phenotype appears similar to the 'benign familial fleck retina' described by Aish and Dajani, and we believe this to be the first published report of such a case since the original description in 1980.

CASE REPORT
A 12-year-old girl was referred after her optometrist noted areas of retinal abnormality on ophthalmoscopy after a routine refraction. She complained of occasional headaches, but had no specific ocular symptoms and was in good general health. Drug or substance abuse was denied. There was no history of maternal illness or nutritional deficiency during pregnancy, and the patient was born at full term. Visual and general development were reportedly normal during infancy and early childhood, and the mother noted no signs of poor daytime or night vision in any of her three children.

The child was of mixed ethnic origin, the non-consanguineous parents both being of mixed Australian aboriginal and white descent, and there was no family history of ocular or systemic disease other than the recent development of maturity onset diabetes mellitus in the mother.

General examination found no evidence of skin depigmentation or vitiligo. Visual acuities were 6/9 right with +0.50 DS/-1.00 DC×180 degrees, 6/6 left with +0.50 DS. Slit-lamp examination of anterior segments and vitreous was normal. Funduscopy revealed a striking pattern of multiple yellow-white flecks situated at a level deep to the retinal vessels, affecting both fundi in a symmetrical pattern (Fig 1). The lesions were distributed in a concentric pattern around the posterior fundus but sparing the optic disc, papillomacular bundle, and the peripapillary area for a distance of 1 disc diameter except inferiorly, where there was involvement to the margin of the optic disc. No part of the equatorial, peripheral, or far peripheral retina was spared. The shape of the flecks was highly variable. The most centrally located lesions were roughly round or ovoid in shape, and approximately the diameter of a third order arteriole. With increasing distance from the central macula, the flecks tended to become much larger and confluent, up to ½ disc diameter in size across the largest dimension. The more peripheral flecks showed greater variability in shape, with linear, geographical, or amoeboid outlines and smooth sinuous margins. On stereoscopic slit-lamp biomicroscopy, the fleck lesions appeared flat, with no evidence of accumulated material within or anterior to retinal pigment epithelial cells. There was no evidence of pigment migration, although several of the larger lesions enclosed areas of normally pigmented retina, giving the appearance of a central pigment clump (Fig 1C, arrowed). No calcification was seen, and choroidal vessels were not visible at the base of the flecks. Fundus fluorescein angiography revealed patchy, fine, irregular hyperfluorescence throughout the fundus which did not correspond to the fleck lesions (Fig 2).

Colour vision testing with Ishihara plates and the Farnsworth dichotomous (D-15) test was normal in each eye. Electro-oculogram (EOG) Arden ratios were at the lower end of the normal range at 1-7 and 1-6 in right and left eyes, respectively. The full field electroretinogram (ERG) was recorded under photopic and scotopic conditions (Fig 3), and was normal except for a slight delay in the b-wave latency from the left eye during 30 Hz flicker stimulation.

At follow up examination 18 months later the headaches had resolved and there were no new ocular symptoms. Visual acuities and fundusscopic appearances were unchanged. Both parents and the only sister of the proband have been examined. All are asymptomatic, and funduscopic examination was normal in each case. The patient’s remaining sibling, an older brother, is asymptomatic and has indicated that he is unwilling to undergo ophthalmic examination.

COMMENT
Our case is characterised by the presence of widespread discrete yellow-white fleck lesions affecting both fundi of an asymptomatic child of mixed Australian aboriginal descent. The macular region is spared and functional testing has revealed no significant abnormality. The absence of pigment migration, atrophy or hypertrophic retinal pigment epithelial cells. Fluorescein angiography is unhelpful in elucidating the precise nature of the retinal dystrophy, since the flecks show...
neither a ‘window defect’ suggesting depigmentation, nor hypofluorescence, which might suggest an abnormal accumulation of material within retinal pigment epithelial cells. Instead, the mild generalised irregular hypofluorescence suggests merely a diffuse abnormality of retinal pigment epithelium.

The occurrence of a marbelised fundus in asymptomatic patients is rare. Aish and Dajani have described an Arab Palestinian family with clinical features which appear to closely resemble those of our patient.1 In this pedigree, the parents were phenotypically normal first cousins. Seven out of 10 of their offspring showed massive invasion of both fundi by bright white or yellow fleck lesions situated behind the retinal blood vessels, and always sparing the macula. Visual findings were normal in all cases. The probable mode of inheritance within this family was autosomal recessive, since both sexes were involved, and the consanguineous parents were unaffected. Krogh et al have described an asymptomatic 31-year-old woman with normal visual acuity, with bilateral retinal flecks in the mid periphery of both eyes.2 The flecks became more dense in the periphery, where they formed a palisade pattern quite unlike that of our case. Functional testing revealed an absent EOG light rise in one eye but was otherwise normal. More recently, a case of bilateral ‘breadcrum’ flecked retinopathy with normal fluorescein angiography and normal electrophysiological findings has been reported in a 9-year-old girl. However, this child also had an idiopathic seizure disorder which had been controlled medically for 6 years, subnormal intelligence, gross motor and developmental delay, and esotropia.3 The size and shape of the retinal flecks in this case are not described in detail, but the published photographs appear to demonstrate a more uniform size and more irregular margins to the flecks than in our patient, with a more linear distribution of flecks and a greater area of normal appearing retina between the flecks.

A marbelised fundus appearance has also been reported as a rare finding in Leber’s congenital amaurosis.4–6 In this variant, yellowish lesions are seen deep to the retinal vessels in a peripapillary distribution, and there may be associated systemic abnormalities, including medullary cystic renal disease (juvenile nephronophthisis).7 The clinical features and absent ERG response of Leber’s amaurosis make confusion with our case unlikely. However, it is interesting to note in such cases that a marbelised fundus may be incidental to visual functional abnormalities.

We suggest that our case represents either a new mutation of the condition described, or possibly an autosomal recessive disorder, since both parents are phenotypically normal.

We wish to thank the Department of Medical Technology and Physics, Sir Charles Gardiner Hospital, for performing the electrophysiological testing.

Brown’s syndrome as a complication of cardiopulmonary resuscitation

EDITOR—Brown’s syndrome is a well recognised ocular motility disorder which may be congenital or acquired. Regardless of aetiology it manifests itself clinically with restriction to both active and passive elevation in abduction, minimal or only slight limitation to elevation in adduction, occasionally a downshoot of the affected eye in adduction and, in more severely affected cases, a primary position hypotropia with an associated abnormal head posture. The head posture consists of a chin-up head position with a face turned away from the affected side or a variable head tilt. Other features less commonly seen are a V-pattern resulting from divergence in upgaze and widenings of the palpebral fissure on adduction.1

CASE REPORT

We report a case of acquired Brown’s syn- drome in a 2-year-old girl without a history of ocular motility disorders. Several months previously she fell into the family swimming pool and was found cyanotic, face down in the water. Her mother, trained in cardiopulmonary resuscitation, rescued her from the pool and successfully resuscitated her using nasal compression, mouth to mouth ventilation, and cardiac massage. The patient was transferred to the Children’s Hospital of Pittsburgh and, after a short period of artificial ventilation, made a full recovery. A computed tomography brain scan could not be reviewed.

After hospitalisation it was noted that the child had developed a mild chin-up head posture. One week later her vision was 20/30 in each eye using Allen figures, she was orthophoric in the primary position of gaze, had a chin-up head posture without head tilt or face turn, and ocular versions revealed limitation of elevation in adduction (Fig 1).

There was no evidence of superior oblique muscle overaction or downshoot in adduc- tion. In addition, the right superior rectus muscle did not act normally and there was some divergence in upgaze which helped to differentiate this entity from an iso- lated left inferior oblique paresis. She demon- strated 100 seconds of arc stereocuity and had normal fusion for both distance and near using the Worth 4 dot test in the primary position of gaze. Magnetic resonance imaging of the orbits was normal and did not reveal any evidence of trochlear disinsertion or swelling. The orbital floor was intact. When the patient was considered sufficiently mature we performed forced duction testing under local anaesthesia which confirmed the diagnosis. The patient was 3 years old at this time.

We did not feel it necessary to subject the patient to general anaesthesia when she first presented in order to confirm the diagnosis, particularly in light of her near drowning event.

This patient has been followed for 18 months and the restriction in elevation in adduction has improved significantly. As the patient did not have a significant head tilt and was orthophoric in primary position surgical intervention was not required.

COMMENT

Acquired Brown’s syndrome has been reported following traumatic events occurring in the region of the trochea; these include peribulbar anaesthesia,2 orbital surgery,3 orbital roof fracture with superior oblique
Benign fleck retina.
