Intraocular production of a cytokine (CINC) responsible for neutrophil infiltration in endotoxin induced uveitis

Yan Guex-Crosier, Arthur J Wittwer, Francois G Roberge

Abstract

Aims/Background—The subcutaneous injection of bacterial endotoxin in Lewis rats produces an acute intraocular inflammation evolving over a 24 hour period. This endotoxin induced uveitis (EIU) is characterised by a biphasic protein exudation and a cellular infiltrate composed of macrophages and polymorphonuclear neutrophils (PMNs). This model was used to study the mechanism of cellular infiltration in ocular inflammation.

Methods—EIU was induced by a subcutaneous injection of lipopolysaccharide (LPS) (S typhimurium) at 350 μg/kg. The levels of cytokine induced neutrophil chemoattractant (CINC) were measured every 2 hours in the serum and in the aqueous humour by ELISA. The intraocular inflammation was quantified by protein measurement and leucocyte counting.

Results—The kinetics of CINC production in the systemic circulation showed a rapid rise, peaking 2 hours after LPS injection, followed by a progressive decline over the next 8 hours. In the eye, the CINC levels increased above the serum levels 10 hours after EIU induction corresponding to the time of cellular infiltration. When leucocyte entry in the eye was inhibited by 56% and 64% with an antiadhesion molecule antibody, there was only a slight reduction in the aqueous humour CINC levels of 9% and 16%, respectively, indicating that CINC was produced by ocular tissue cells. The specific effect of CINC in the eye was confirmed when a direct intraocular injection of 250 ng of purified CINC was followed by significant PMN infiltration, in the absence of protein exudation.

Conclusion—The data indicate that the production of the CINC chemotactic factor by ocular tissue participates in the inflammatory reaction in EIU.

(Br J Ophthalmol 1996;80:649–653)

Bacterial endotoxins are associated with a variety of pathophysiological disorders. Endotoxins have been implicated in liver and kidney failure, as well as in adult respiratory distress syndrome. The biological activity of endotoxins has been attributed to the lipid A moiety of cell wall lipopolysaccharide (LPS). The best studied effect of endotoxin is the induction of cardiovascular shock. Experimental studies uncovered a cascade of inflammatory cytokines mediating the vascular collapse. Tumour necrosis factor α (TNF-α) and interleukin 1 β (IL-1β) play a critical role in triggering this reaction. Other mediators, including IL-6, IL-8, lipid derivatives such as prostaglandin E2 (PGE2), leukotriene B4, and platelet activating factors (PAF), are also involved. Several cell types participate in this response, with the macrophage and the vascular endothelial cells playing a central role.

An intraocular inflammation termed endotoxin induced uveitis (EIU) is also caused by a systemic injection of endotoxin. EIU sensitive strains include Lewis rats, C3H/HeN mice, and albino rabbits. The ocular disease in rats is characterised by an early progressive protein exudation within 2–4 hours after LPS injection, followed by a cellular infiltration starting 6–10 hours later and accompanied by a surge in protein entry into the eye. The inflammation is maximal at 24 hours, and lasts approximately 48 hours. The main infiltrating cell types are the polymorphonuclear neutrophils (PMNs) and the monocytes. An advantage of this model is that it allows for a separate analysis of the inflammatory mechanism inside the eye in parallel and in association with the intravascular compartment.

We used the EIU model to analyse the nature and kinetics of chemotactic cytokines involved in acute anterior uveitis. These chemokines constitute a family of factors regulating the traffic of leucocytes from the blood to peripheral tissues. This family is subdivided in the two subgroups CXC and CC according to the presence or absence of one amino acid between two shared conserved cysteine residues. This structural division corresponds to distinct roles. The CXC family mainly attracts PMN leucocytes, and the CC family is active on lymphocytes and monocytes. IL-8 is one of the best known member of the CXC family. IL-8 is produced by numerous inflammatory and organ specific cells. In rodents, the function of IL-8 appears to be accomplished by cytokine induced neutrophil chemoattractant (CINC). CINC is an 8 kDa peptide of the CXC family with a 70%–72% structural homology to the human GRO factors. Functionally, CINC shares more similarity with IL-8. However, contrary to IL-8 which can attract both PMNs and T lymphocytes, CINC chemotaxis is restricted to PMN cells. Like IL-8, the secretion of CINC is
induced by LPS and by various cytokines such as IL-1β and TNF-α.17

We report a study of the dynamics of intravascular CINC production in relation to its intravascular levels, and the role of this cytokine in the mechanism of EIU.

Materials and methods

INDUCTION OF OCULAR INFLAMMATION
EIU was induced in male Lewis rats weighing 250 to 275 g (Charles River, Raleigh, NC, USA) by a subcutaneous injection of Salmonella typhimurium LPS (Lot No 10720JA, Difco Laboratories, Detroit, MI, USA) at 350 μg/kg in 0.1 ml phosphate buffered saline (PBS). At the indicated time points, serum and aqueous humour were collected after euthanasia by carbon dioxide inhalation. The aqueous humour of the two eyes of each rat were pooled, and 1 μl was placed on a silanated glass slide (Digene, Beltville, MD, USA) and allowed to dry at room temperature. The cells were counted under a microscope after staining with 0.4% Trypan blue solution under a cover slip. The remaining aqueous humour was centrifuged at 10 000 g to remove the cells and the protein content was measured by the Coomassie colorimetric assay (Fierce, Rockford, IL, USA) in duplicate in microtitre plates, by reference to an albumin standard. CINC levels were measured as indicated below.

INHIBITION OF INTRAOCULAR CELL INFILTRATION WITH ANTIADHESION MOLECULE ANTIBODY
In some experiments, the cellular infiltration into the eye was inhibited by an intraperitoneal injection of 2.0 mg per rat of the antibody (Ab) 1B6 (generous gift of Dr K Sokolowski, RepliGen Corporation, Cambridge, MA, USA) 4 hours after LPS administration. 1B6 is a mouse antirat monoclonal Ab blocking cellular adhesion through the CD11b chain of the Mac-1 adhesion molecule. 1B6 is an IgG, and does not produce complement cell lysis. The aqueous humour was collected 16 hours after LPS injection for cell counting and measurement of the CINC level.

INTRAOCULAR CINC INJECTION
The rats were anaesthetised with sodium pentobarbitone injected intraperitoneally at 50 mg/kg (Anpro Pharmaceutical, Arcadia, CA, USA) and with topical application on the eye of proxymetacaine hydrochloride (proparacaine hydrochloride) 0.5% (Alcon Inc, Humacao, Puerto Rico). The anterior chamber was opened through a corneal stab incision with a 15° Alcon ophthalmic knife and partially drained of aqueous humour. Synthetic CINC peptide, certified to be free of LPS by Peptide International (Louisville, KY, USA) was injected at 250 ng in 10 μl PBS in one eye with a glass micropipette. The contralateral eye received PBS alone. The aqueous humour was collected 4 hours later for protein measurement and cell count (optimal time determined by preliminary clinical observations of the anterior chamber at 1, 2, 3, 4, 6, and 8 h after injection).

SERUM AND AQUEOUS HUMOUR CINC MEASUREMENT
CINC levels were measured by sandwich enzyme linked immunosorbent assay (ELISA) as described previously.19 Briefly, Immulon-1 plates (Dynatech Laboratories Inc, Chantilly, VA, USA) were coated overnight at 4°C with an affinity purified goat anti-CINC Ab (7 μg/ml, 100 μl/well) diluted in 0.1 M bicarbonate buffer pH 9.6. Additional binding sites were blocked by a 2 hour incubation at 37°C with 5% milk in 50 mM TRIS-HCl normal saline +0.05% Tween (TBS-T) buffer pH 7.5. Dilutions of serum and aqueous humour samples in TBS-T (100 μl/well) were incubated for 2 hours at 22°C. A standard curve was constructed with purified CINC (Peptide International, Louisville, KY, USA) at a concentration range of 20.00 to 0.35 ng/ml. Captured CINC was reacted with rabbit anti-CINC (Peptide International) at 1:20 000 for 2 hours at 22°C, followed by alkaline phosphatase labelled goat anti-rabbit IgG for 45 minutes. The reaction was developed with the Gibco BRL ELISA amplification system (Gibco BRL, Gaithersburg, MD, USA).

Figure 1 (A) Kinetics of protein exudation and cellular infiltration in the eye after subcutaneous lipopolysaccharide (LPS) injection (350 μg/kg). Each time point represents five animals. The protein concentration was measured by Coomassie blue microassay. The number of leucocytes per μl was counted after drying and staining with trypan blue. The protein exudation followed a biphasic curve with the highest peak approximately synchronous with the cellular infiltration. (B) Serum and aqueous humour (AH) samples were collected at 0, 1, 2, 3, 4, 6, 8, 10, 12, and 16 hours after subcutaneous LPS injection. Cytokine induced neutrophil chemotactants (CINC) levels were measured by sandwich ELISA, with reference to a standard curve of purified CINC. Each time point represents the average (SEM) of measurements from five animals. An intraocular positive gradient of CINC is observed 10 hours after LPS injection.

**Results**

**KINETICS OF INTRAOCULAR INFLAMMATION AFTER LPS INJECTION**

Protein leakage was detected in the anterior chamber of the eye 2 hours after subcutaneous LPS injection. The kinetics of the exudation are shown in Figure 1A. The protein level rises early to a peak at 4 hours followed by a slow decrease broken by a sharp surge beginning between 8 and 10 hours after LPS. Cells were first observed in the eye at the 10 hour time point, and their number increased rapidly between 10 and 12 hours (Fig 1A).

**KINETICS OF SERUM AND OCULAR CINC LEVELS**

In the serum, the level of CINC peaked 2 hours after LPS injection with a mean concentration of 734 (SEM 54) ng/ml, and decreased progressively during the following 8 hours (Fig 1B). In the aqueous humour CINC was detected 2 hours after LPS injection, and started to increase above the serum level at 10 hours (Fig 1B). The increase of CINC concentration in the aqueous humour above the serum levels, in the later time points, corresponded to the time of entry of leucocytes into the anterior chamber of the eye (Table 1).

**Production of CINC in the eye**

In order to differentiate if the CINC measured in the eye was produced locally and attracted the leucocytes, or was secreted by the infiltrating cells themselves, we inhibited the cellular adhesion and assessed its effect on the intraocular CINC levels. Inhibiting leucocyte adhesion by treating the animals with 1B6 caused a 56% reduction in cellular infiltration of the eye with 321 (12) cells/μl compared with 730 (155) cells/μl in the control group (p=0.014) (Fig 2). However the aqueous humour CINC level in these 1B6 treated rats decreased by only 9% compared with the control treated rats (p=0.827) (Fig 2). In a second experiment the 1B6 treatment produced a 64% reduction in cells infiltration accompanied by only a 16% decrease in intraocular CINC levels compared with the controls.

**STATISTICAL ANALYSIS**

The unpaired Student's t test was used for the comparison of means of protein or CINC levels between groups, and the paired t test was used for the comparison of measurements between eyes injected with CINC and the contralateral control eyes. The cell counts between different groups of rats were compared with the Mann-Whitney rank sum test. Differences were considered significant at a p value ≤ 0.05. The calculations were done with the STATVIEW software.

**Table 1** Correlation of the positive cytokine induced neutrophil chemoattractant (CINC) gradient towards the anterior chamber with leucocyte infiltration. Lewis rats were injected subcutaneously with lipopolysaccharide at 350 μg/kg. Serum and aqueous humour were collected at the indicated time points.

* CINC was measured in the serum and in the aqueous humour by ELISA, and a gradient representing the intraocular level minus the serum level was determined. Each time point represents the average (SEM) of measurements from five animals.
Injection of CINC in the eye

The chemotactic effect of a direct intraocular injection of CINC was evaluated. When CINC was injected in the anterior chamber of the eye of naive rats there was a significant influx of cells into the aqueous humour by Giemsa stain; the cells were almost exclusively PMNs (not shown). The mean cell counts in the CINC-injected eyes (n=5) was of 630 (213) cells/μl compared with 31 (8) cells/μl in the eye injected with PBS alone (p=0.047) (Fig 3). CINC had no effect on protein exudation. The mean protein concentration was of 1.46 (0.17) mg/ml in the CINC injected eyes and 1.36 (0.16) mg/ml in the control eyes (p=0.59) (Fig 3). In naive non-injected rats, the mean protein concentration was 1.41 (0.08) mg/ml.

Discussion

The study of animal models of endotoxin shock and the injection of low doses of endotoxin in human volunteers helped understand the inflammatory cascade triggered by LPS. In the blood, the LPS molecule attaches to a carrier protein (LBP), and in this complex form interacts with the CD14 cell surface receptor to activate monocyte, TNF-α and IL-1β are released, causing a cardiovascular shock. TNF-α can be detected in circulation half an hour after LPS injection and the levels peaks 30 minutes later. IL-1β appears shortly after TNF-α and has a synergistic effect on the production of other inflammatory cytokines such as IL-6 and IL-8. The circulating array of cytokines induced by LPS is probably responsible for the early rupture of the blood-aqueous barrier that we observed in EIU. During the early phase of EIU, the passive entry of the inflammatory cytokines TNF-α and IL-1β from the circulation probably induces the intraocular production of factors such as CINC by ocular tissue cells. Indeed the messenger RNA of several cytokines has been detected in the eye of EIU. The intraocular injection of TNF-α was shown to induce IL-6 production in the eye. In addition, ocular specific cells in culture were able to produce inflammatory mediators. A large population of immunocompetent cells such as resident macrophages and dendritic cells was also observed in the eye. In our observations the small amount of CINC found in the eye up to 8 hours after LPS injection appears to come from the circulation with the protein exudate. At this time the gradient of CINC is directed towards the intravascular compartment and cells are not infiltrating the eye. Cellular infiltration of the anterior chamber occurs approximately 10 hours after LPS, when the CINC gradient is favoring the eye. This later increase in CINC presumably comes from ocular cell synthesis, because at this time the serum levels are lower than in the eye. In addition, these CINC levels are only slightly affected when leucocyte infiltration is reduced by anti-adhesion molecule Ab treatment. The reported in vitro chemotactic dose-response curve of CINC increases from 0.8 ng/ml to a maximum at 250 ng/ml with a half maximum level of 8 ng/ml. The CINC gradient level of 6 to 104 ng/ml that we measured in the eye correlates well with these doses. We also confirmed the chemotactic effect of CINC in the eye by direct intraocular injection. The observed effect was purely chemotactic for PMN leucocytes and did not induce any protein infiltration. In EIU, the activation of circulating leukocytes by LPS certainly increases the ability of the cells to enter the eye. However, the activation of PMNs was not necessary for the cells to migrate in the eye in response to the tested dose of CINC. One of the contributing factors of ocular infiltration in EIU is the induction of adhesion molecules on the leucocytes and the vascular endothelium induced by LPS. In humans the CD11/CD18 adhesion molecule on PMN cells is upregulated by IL-8. The high levels of CINC in the blood of rats may play a similar role contributing to the priming of leucocytes for ocular infiltration. The shifting of the chemotactic gradient towards the eye as seen here with CINC during the course of EIU may occur with other chemotactic molecules. The use of the EIU model to study these chemotactic gradients should help to unravel the sequence of events leading to ocular infiltration in uveitis.

Van Guex-Crosier was supported by a grant from the Swiss National Fund for young Researchers and from the Société Académique Vaudoise (Pondation Fern Moffat). We would like to thank Dr Karen Sokolowski and Dr Marc Bree from RepliGen Corporation for providing the 1B6 antibody and Dr Terrence Kinsey for his helpful suggestions.
