A new substrain of the non-obese diabetic mouse which develops cataracts (NOD/Ba/Lop19)

Editor,—The non-obese diabetic (NOD) mouse is a spontaneous model of type 1 (insulin dependent) diabetes mellitus, frequently used in diabetes research. The colony at the medical college of St Bartholomew’s Hospital (NOD/Ba) was established in 1987 and some 55% of females and 15% of male mice spontaneously develop diabetes by 30 weeks of age. Cataracts are not a characteristic normally found in NOD mice but were observed during routine inspection in 1988. All animals in the substrain NOD/Ba/Lop19 now spontaneously develop cataracts in both eyes (typically at 104–109 days of age). There are diabetics in both eyes (typically at 104–109 days of age). There are differences between NOD/Ba/Lop19 and the other mice of the colony with puberty, gestation period, teeth eruption, and eye opening all taking place later. Cataracts of the type seen are often the result of metabolic disturbances; however, although blood glucose levels greater than 12 mmol/l are known to cause cataracts in experimental models, their development in NOD/Ba/Lop19 is not related to the development of diabetes (normally at 112–133 days) as they occur before blood glucose levels exceed 11.5 mmol/l. This is unusual in that cataract formation in other susceptible laboratory rodents usually precedes the development of a general disease state.

The cataracts initially take the form of a visible dense white sclerotic central area (see Fig 1), accompanied by clouding of the lens itself, and a bile dense white sclerotic central area (see Fig 1). The condition is progressive and, although only 50% of mice are affected by 220 days of age, by 300 days of age all mice in the colony have bilateral cataracts. The cataracts are not abnormal in other organs, and no abnormality has been noted in other organs. The cataracts are not abnormal in other organs, and no abnormality has been noted in other organs. However, some mice have other abnormalities, such as a thick band of sclerotic material on the right hand side.

The support of the Joint Research Board of St Bartholomew’s Hospital is gratefully acknowledged.

Cortically visually impaired children

Editor,—While Hoyt and Fredrick rightly state the heterogeneous aetiology of cortical visual impairment (CVI) in children,1 we were disappointed to read an unjustified dismissal of the value of electrophysiological studies in these cases. They fail to quote any electrophysiological studies more recent than 1979 in their review, of which there have been a not inconsiderable number. As for our own work we have found that a normal flash VEP indicates statistically and clinically a better prognosis in blind babies with non-ocular visual impairment even though we would concede that in some cases flash VEPs can be normal in CVI.1 It is therefore clinically useful to perform evoked potential studies in these children, a position endorsed by the commentary in the same issue of BJO,1 which states that electrophysiological investigations are mandatory in the investigation of babies with poor visual contact. We endorse this sentiment and although accepting the limitations of the technique, feel that VEP investigations provide valuable objective information in the assessment of these infants. Hoyt and Frederick rightly point out that further work is required in this infant CVI but not even to attempt any review of work within the past 20 years—never mind the most recent—is at best misleading and at worst scientifically unacceptable.

Reply

Editor,—We thank Clarke and Mitchell for their thoughtful comments on our editorial on cortical visual impairment (CVI). We are somewhat bemused by the notion that the passage of time invariably invalidates good clinical studies. Our editorial did not go into detail about VEPs and CVI because of space limitations and the focus of that editorial. We meant only to imply that VEPs had been less useful than we all hoped they would be in evaluating this difficult group of visually impaired children. We do not disagree with Clarke and Mitchell that intact flash VEPs usually indicate a better visual outcome than if the VEPs are abnormal or absent. Similar results have been reported by Taylor and McCulloch.2 Regrettably, in our studies of children with cortical visual impairment the group of patients with intact flash VEPs represents only a small portion of those we care for. In the remaining larger group of patients with abnormal VEPs we have not found good correlation with the ultimate visual outcome. Moreover, in children with neurological disorders, flash VEPs are often abnormal even when the patient is well sighted.3 The problem then is how to interpret an abnormal VEP in a child with CVI. This is where VEPs have been disappointing and frequently misleading VEP mapping may indicate a significant improvement over standard flash VEPs. Witing et al1 reported that VEP mapping in 50 children with permanent CVI was always abnormal and showed good correlation with computed tomography. However, whereas the conventional VEP recordings were abnormal in only 50% of cases and with much less good correlation. We, therefore, look forward to further studies of VEPs demonstrating improved techniques that provide better prognostic value when evaluating the abnormal VEP in a child with CVI.

We apologise for any confusion caused by the terseness of our discussion. We encourage Clarke and Mitchell to continue their VEPs of children with CVI and look forward to reading their results in the future.

Automated perimetry by optometrists in patients at low risk of glaucoma

Editor,—The letter by Dayan et al1 raises some interesting questions regarding the examination and referral of patients by optometrists for further investigation in relation to open angle glaucoma.

While the authors base their comments largely on anecdotal evidence from a series of only 11 subjects from one referral source, there are nevertheless some important points to be answered from these comments.

Firstly, the College of Optometrists guidelines offer guidance based on clinical evidence to optometrists conducting eye examinations. They specifically encourage optometrists to conduct the appropriate tests on any individual patient as a matter of best practice. In the case of glaucoma, recommendations are made that visual field tests should be conducted on subjects over the age of 40, those with a family history of glaucoma, and those with suspicious optic discs or other risk factors.

The majority of visual field tests used in optometric practice are based upon static
perimetry (College of Optometrists annual clinical survey, 1998) and decisions then need to be made on the results obtained. Therefore, if one or two points are missed on a central field test does that mean an abnormality is present? The optometrist needs to make a judgment on this issue in the light of the complete clinical findings rather than simply exert a pass/fail criterion from a screening test.

Not surprisingly most glaucoma patients in hospital clinics are referrals from optometrists but evidence is at the cost of a relatively high false positive rate. Not surprisingly also, visual field test designers are continually trying to develop programs with high specificity and high sensitivity, which help the user to make an appropriate decision regarding normal or abnormal findings and thus referral.

Whether the optometrist refers a patient to the general practitioner for further investigation is influenced by a number of factors. Optometrists are legally required to refer patients if an abnormality is suspected or found. Therefore, realistically, individual practitioners are more concerned about missing pathology than referring false positives. This feeling is further strengthened by legal cases reaching the General Optical Council where optometrists have been sued (successfully) for not detecting and referring ocular pathology, an attitude which they have little option but to refer to the hospital eye service. Informing the optometrist of the outcome of all referrals is undoubtedly good practice but we do not then know the significance and impact on the false positive referral rate. It is the guidelines themselves that are the problem.

We note that there is some disquiet among optometrists as well as ophthalmologists about the guidelines. An area where a patient will be referred with a “normal” eye is that of pathology. There must be a grey area where a patient will be referred with a reasonable measure of doubt as to the presence of an abnormality. What is an acceptable false positive rate with respect to referrals to a hospital eye clinic?

Better assessment criteria in which the referral process could be improved is by a formal notification system from ophthalmologists to optometrists to let individual optometrists assess the accuracy of their clinical findings/decisions/results of the tests they refer. The health service referral forms are designed to allow this to happen since the patient can be asked to sign giving consent to the general practitioner or optometrist to pass information back to the referring optometrist. Ideally the ophthalmologist will send a copy of the reply to the general practitioner and to the referring optometrist. Currently and historically this process does not happen in many areas of the country (personal communication with members).

Reply
Editor,—We thank Dr Stevenson for his interest in our letter. Though we recognize that the evidence is anecdotal there has been no systematic study to justify the use of routine visual field screening in patients over 40 attending their optometrist. The best way the improve the positive predictive value of visual field screening would be to apply it to a group with a higher pretest probability of having pathology—for example, patients over 60 years of age. We doubt that forthcoming technological developments will improve the trade off between sensitivity and specificity to a point where routine screening of patients over 40 would be reasonable. Furthermore, a test of adequate positive predictive value is a prerequisite for a screening programme not a post hoc modification.

With regard to the legal position, this has in part been created by the guidelines themselves since a practitioner who does not comply with them can be held to have been negligent.

The fault does not lie with individual optometrists who cannot be blamed for making the referrals; having identified a field defect they have little option but to refer to the hospital eye service. Informing the optometrist of the outcome of all referrals is undoubtedly good practice but we do not then know the significance and impact on the false positive referral rate. It is the guidelines themselves that are the problem.

We note that there is some disquiet among optometrists as well as ophthalmologists about the guidelines. An area where a patient will be referred with a “normal” eye is that of pathology. Author’s reply
Editor,—I thank Dr Griffiths for his reply to my original comments. However, I would like to answer some of the points he raises.

The use of visual field screening in patients above the age of 40 in optometric practice is based upon the fact that the incidence of glaucoma increases above that age. Therefore, measuring macular sensitivity and visual fields and combining this with assessment of the optic disc is highly relevant in that group of the population. The highest positive predictive value (PPV) is demonstrated when information on all three factors is included.

Logically it follows that the PPV of visual fields as a “stand alone” test increases if it is only used in a group with a higher cut off age—that is, 60 years by day. As suggested by Griffiths, given the age related nature of many ocular conditions including glaucoma. This approach is likely to miss a significant number of possible early chronic simple glaucoma cases. Conditions other than glaucoma may also be detected by routine visual fields testing, a point made in Griffiths’s original letter.

The legal position of the college guidelines may be misunderstood by practitioners in that, by not complying with them, he suggests that a practitioner may be held negligent. This is not the case since the guidelines are not set by the General Optical Council as law but are simply College of Optometrists professional guidelines given to members to represent current best practice.

Most optometrists feel that if they receive feedback on referrals to indicate a high false positive referral rate, referral criteria would be modified to correct this problem. Recent ophthalmological opinion does suggest that feedback on referrals will help case finding.

Finally, I do agree that it would be welcome and timely to have dialogue between ophthalmologists and optometrists regarding the age above which individuals should have their visual fields tested at routine eye test appointments. Much of the misunderstanding regarding referrals in this area could then be clarified.

This is also relevant in light of the current review of the GOC referral guidelines to optometrists relating to the present obligation to refer to a general practitioner when an abnormal finding is detected in the routine eye test.

BOOK REVIEW

The editors of Ida Mann’s autobiography, Elizabeth Buckley and Dorothy Potter, have undertaken a task of a true devotion. Through their long standing respect and admiration for this giant of 20th century ophthalmology, the authors have successfully brought together an excellent book which reviews the somewhat meandering autobiography which Ida Mann herself wrote.

For those who are interested it is an extremely fascinating account of individuals who helped to form Ida Mann’s career from her early days at Moorfields and Oxford onto her period in Australia and the continuing research that she did there on Aboriginal demographics.

The autobiography itself provides a unique insight into the enormous energy, but even more so into the approach, which Ida Mann took to her research work. Undoubtedly, these were driven by a great interest in her topics. In addition, she paid great attention to detail and this is highlighted in the book itself with some
