Numerous subretinal hypopigmented tracks with small haemorrhages were noted in the superonasal retina, and perivascular haemorrhages were observed around the inferior branch of the central retinal vein (Fig 2). Fluorescein angiography showed numerous hyperfluorescent tracks without dye leakage. The patient’s blood test revealed a slightly elevated white blood cell count (10 200 × 10³/l; normal <9000) and elevated IgE in the serum (680 U/ml; normal <250).

On the following day pars plana vitrectomy was performed and the worm was found partially migrated into the subretinal space of the macula. The worm was aspirated successfully through a 20 gauge silicone tipped needle and submitted for histopathological study; however, it was lost during transportation to a different laboratory. Parasitological study of the patient’s serum detected an antibody to *Dirofilaria*. Six months after surgery, the patient’s visual acuity was 20/20 in the right eye and 20/100 in the left. No inflammation was present in the anterior segment or vitreous cavity bilaterally. Ophthalmoscopic examination disclosed a white worm, approximately 3 disc diameters in length, equivalent to about 4.5 mm, moving slowly in the macula at the epiretinal. Epiretinal and intraretinal haemorrhages were observed in and around the macular region. The body of the worm was tapered at one end and slightly rounded at the other (Fig 1). A round, preretinal haemorrhage was observed on a branch of the superonasal retinal artery, which could have been the route of entry into the eye.

**CASE REPORT**

A 38 year old woman complained of decreased visual acuity in her left eye of 5 days’ duration. Her medical history was unremarkable. The patient had two pet dogs, and she had not travelled to foreign countries in recent years. On examination, her corrected visual acuity was 20/20 in the right eye and 20/100 in the left. No inflammation was present in the anterior segment or vitreous cavity bilaterally. Ophthalmoscopic examination disclosed a white worm, approximately 3 disc diameters in length, equivalent to about 4.5 mm, moving slowly in the macula at the epiretinal. Epiretinal and intraretinal haemorrhages were observed in and around the macular region. The body of the worm was tapered at one end and slightly rounded at the other (Fig 1). A round, preretinal haemorrhage was observed on a branch of the superonasal retinal artery, which could have been the route of entry into the eye.

**COMMENT**

Our patient owned two dogs, and her ocular findings could be differentiated from toxocariasis, in which only larvae of *Toxocara canis* can infect humans. The length of the *Toxocara* larva is about 400 μm, and grows no longer. Although no direct microscopical evidence of *Dirofilaria* infection was obtained in our patient, a positive antibody to *Dirofilaria* in the serum indicated its infection. There have been many reports of intraocular filariasis; however, the filariae were removed and identified in only six of 56 cases reviewed by Beaver in 1989. Direct parasitological microscopic examination is necessary for accurate diagnosis, but serological study can be helpful, as shown in the present case.

Various types of management for intraocular parasites have been reported. Direct photocoagulation to the worm body has been successfully reported in cases with filaria-like worms and in one case with insect parasites. It has been suggested that photocoagulation denatures the parasite proteins and mitigates the immune reaction. If the parasite is located in the posterior pole of the retina, however, photocoagulation may cause permanent visual impairment, and surgical removal should be selected. Furthermore, photocoagulation would make parasitological identification impossible. Preretinal or subretinal parasites were retrieved successfully by pars plana vitrectomy in several reported cases. In the present case, the visual acuity was still 20/50 6 months postoperatively. The migrating worm may have caused considerable damage to macular function, therefore, we believe that intraocular parasites should be removed as soon as possible.

The authors are grateful to Dr Keizo Yamaguchi for parasitological examination and Mr Shingo Yama-zaki for fundus photographs.

**LETTERS TO THE EDITOR**

**Surgically removed submacular nematode**

Editor,—Intraocular filariasis is an uncommon disease in civilised countries. In only a few cases has the worm been surgically removed from the posterior portion of the eye and identified. In this report we describe a patient who had a filaria-like worm in an epit-macular and/or submacular lesion, which was successfully removed surgically.

**CASE REPORT**

A healthy 21 year old woman, who had been wearing daily disposable contact lenses for 1 year, wore her lenses for 4 hours on 1 day and then stored the lenses in preserved saline solution overnight in a new contact lens case. She rewore the lenses for a further 3 hours the following day. She reported that this was the first time that she had done this. She then developed a painful left eye. This was initially treated as conjunctivitis by her general practitioner and local accident and emergency department. After 2 weeks her local eye unit suspected acanthamoeba keratitis and performed an epithelial scrape that “revealed amoeba species”. She was then referred to our unit for our opinion.

On examination her visual acuity was reduced to 6/18 in the left eye. There was conjunctival injection and a mild scleritis. The patients

**Acanthamoeba keratitis occurring with daily disposable contact lens wear**

Editor,—Up to 92% of cases of acanthamoeba keratitis occur in contact lens users of all types. Failure to disinfect soft contact lenses and the use of chlorine disinfection systems are major factors accounting for the increase in cases of acanthamoeba keratitis. It is thought that “daily disposable” contact lenses, which require no disinfection, will have a much lower risk for the development of all forms of infectious keratitis. We report a case of acanthamoeba keratitis occurring in a daily disposable contact lens wearer. We believe this is the first such reported case.

**References**

Corneal epithelial and perineural infiltrates (Figs 1 and 2). She had a mild anterior uveitis. Acanthamoeba was strongly suspected. Corneal epithelium was removed for microscopy, culture, and histology. Her contact lens case and solutions were also sent for culture. Acanthamoeba was cultured from both corneal epithelium and lens case, but not the lens solutions. She was treated with topical polyhexamethylene biguanide 0.02% (PHMB) and prednisolone 0.3 % as well as oral furibric profen (Froben, Knoll Ltd, Nottingham). Six weeks after diagnosis she was asymptomatic with a visual acuity of 6/9. The eye was quiet, though some corneal infiltrates remained.

**COMMENT**

Acanthamoeba are free living protozoa commonly found in soil and water, including the anterior chamber of normal eyes. Acanthamoeba are free living protozoa commonly found in soil and water, as well as in the anterior chamber of normal eyes. Acanthamoeba keratitis is an uncommon but potentially devastating condition. The number of cases diagnosed in the United Kingdom has steadily risen over the past 20 years owing to increased contact lens wear. A case of acanthamoeba keratitis occurred in a daily wear disposable lens wearer.  

Radford et al found that daily wear disposable contact lenses were associated with greatly increased risk of acanthamoeba keratitis compared with other lens types and wear systems. Multivariable analysis showed that this was largely attributable to a lack of disinfection, the use of non-sterile saline, and the use of chlorine based disinfection rather than alternative chemical systems. It was concluded that 80% of cases of acanthamoeba keratitis could be prevented by the adequate use of an effective disinfection system. It was felt that the "low care" philosophy of daily wear disposable lenses had become "no care" in practice. Daily disposable contact lenses, in which the lens is discarded after 1 day's wear only, were introduced in 1995. When used properly the lens is discarded after 1 day's wear only, had become "no care" in practice. A case control study of acanthamoeba keratitis in contact lens users: a case control study. BMJ 1995;310: 1567-70.  

Acute acanthamoeba keratitis can lead to a rapid destructive course of disease with severe loss of visual field and electoretinograph abnormalities. The lesion defined zones of the retinal receptor cells; however, the cause of the disease remain unclear. There is also no established conclusion about progression of visual field loss. With a multifocal ERG (m-ERG), a large number of retinal locations can be stimulated simultaneously and local responses can be extracted independently in a single recording session. High resolution topographic mapping of retinal function also is possible. A previous report indicates its efficiency in the diagnosis of AZOOR. There are no reports about the clinical course. Thus, using m-ERG and static perimetry (Humphrey 30-2), the alteration of retinal function in a clinical course of a patient with AZOOR was investigated.

**Clinical course of acute zonal occult outer retinopathy in visual field and multifocal electoretinogram**  

**EDITOR.—**Patients with acute zonal occult outer retinopathy (AZOOR) may present with a normal fundus examination and almost normal fluorescein angiography (FA), despite severe loss of visual field and electoretinograph (ERG) abnormalities. The lesion defined zones of the retinal receptor cells; however, the cause of the disease remain unclear. There is also no established conclusion about progression of visual field loss. With a multifocal ERG (m-ERG), a large number of retinal locations can be stimulated simultaneously and local responses can be extracted independently in a single recording session. High resolution topographic mapping of retinal function also is possible. A previous report indicates its efficiency in the diagnosis of AZOOR. There are no reports about the clinical course. Thus, using m-ERG and static perimetry (Humphrey 30-2), the alteration of retinal function in a clinical course of a patient with AZOOR was investigated.

**CASE REPORT**  

A healthy 26 year old woman presented to our outpatient clinic complaining of acute onset of visual disturbance in her left eye. Her corrected visual acuity was 20/20 in her right eye, and 20/100 in her left. The pupils were equal and reactive normally. Slit lamp and fundus examination, computed tomography, magnetic resonance imaging scan, and general examination were normal. HVF 30-2 demonstrated blind spot enlargement breakthrough of the inferotemporal periphery in the left eye (Fig 1, top). Full field ERG showed grossly reduced A and B waves in the left eye. The PA showed slight leakage from peripapillary capillaries. Indocyanine green (ICG) angiography showed slight hypofluorescence of the macular area at a late phase. Analysis of the mean deviation in HVF over the clinical course corresponded with the visual acuity (Fig 1, bottom). In addition, m-ERG (Veris III, Tomey, Nagoya, Japan) was analysed during the clinical course. In this examination, the fundus was divided into four foci and the sum of amplitudes in each group was measured (Fig 2, top). In the left eye, the sum of amplitudes was altered individually but all of them were affected during the clinical course. Only in the inferotemporal area did it correspond with HVF. The values in the right eye were about 5000 μV in each focus. This is almost the same as normal volunteers in our clinic (data not shown).

**COMMENT**  

AZOOR may be precipitated by various retinal disorders and is characterised by rapid visual field loss which cannot be explained by the ophthalmoscopic changes resulting from the initiating disease. The ERG is abnormal, indicating that the field loss is due to retinal dysfunction. The cause of the acute damage to sharply defined zones of the retinal receptor cells in the absence of visible fundus changes in patients with AZOOR is unknown. In some previous reports, an apparent response to corticosteroid therapy suggested that an inflammatory and perhaps an immune reaction may play a part in the disease; however, there is no specific evidence for an immune abnormality. An infectious aetiology could also be the cause of AZOOR.

**Figure 1** (Top) Ratio images of Humphrey 30-2 visual fields in the left eye. (Bottom) The relation between clinical course and mean deviation (MD) of Humphrey 30-2 visual field and visual acuity in the left eye. Asterisks indicate the day in which multifocal ERG was analysed. The roman numerals correspond with raw images in the upper part of the figure.
The findings of AZOOR that we observed in our patient suggest that the retinal recovery assessed by m-ERG was different for the inferotemporal retina and was delayed compared with visual acuity and HVF. Perhaps this delayed retinal recovery reflects a subtle microcirculatory disturbance that can not be clearly detected by FA or ICG. Slight leakage in FA and slight hypofluorescence on the late phase in ICG would suggest such a microcirculatory disturbance.

When better understanding of the aetiology and pathophysiology of AZOOR is available, the clinical response to appropriate therapy may perhaps best be followed by m-ERG.

Hypotonic maculopathy following pneumatic retinopexy: a UBM study

EDITOR,—Pneumatic retinopexy is a promising surgical alternative in selected cases of retinal detachment. We report a rare complication, to our knowledge the first ever reported, of this procedure—namely, hypotonic maculopathy, caused by a wound dehiscence on a patient who had previously undergone a standard extracapsular extraction with posterior chamber implant. Ultrasound biomicroscopy (UBM) proved to be a valuable adjunct in both the diagnosis and management of this complicated case.

CASE REPORT
A 63 year old white man, complaining of a shadow in his right visual field, was referred to our department in April 1997 for further management. Ocular history was notable for multifocal choroidopathy. He tolerated the procedure well and made a rapid visual recovery. Two weeks postoperatively, the pressure normalised (IOP 12 mm Hg), maculopathy was reversed, and visual acuity improved to 20/50.

Hypotonic maculopathy is an unusual and, to our knowledge, the first reported complication of this kind after pneumatic retinopexy. We hypothesise that the original cataract wound did not heal properly and the additional cryoprobe manipulation caused the following.

Hypotonic maculopathy

Figure 1 UBM picture of right eye showing the external part of the dehiscence cataract wound, as a narrow slit, before repair (area between arrows). There is a full blown hypotonic maculopathy in this eye, with VA 20/200.

Figure 2 UBM picture of right eye showing the same area after repair. Note that the external part of the wound is totally closed (area between arrows) while internal wound gap appears to be more pronounced postoperatively. However, at this point the leak is rectified. IOP and macula are normal with VA of 20/50.

Between October 1997 and November 1997 he was presented to our unit on three occasions complaining of further deterioration of vision to 20/200, IOPs between 3–5 mm Hg, and a full blown hypotonyous maculopathy. After 3 months of hypotony of "unknown origin", a diagnosis was made by a glaucoma specialist using indention gonioscopy revealing a dehiscence of the cataract wound. A preoperative UBM study confirmed the presence of an internal wound gap, behind the limbus, superotemporally, 3 mm in circumference. Ultrasonically the wound dehiscence was described as a narrow slit (Fig 1) with a flat adventent bleb above which was not apparent clinically. A surgical repair of the wound was decided upon. Intraoperatively no definite dehiscence could be clinically identified. Balanced salt solution through a 30 gauge needle was repeatedly injected under pressure to the anterior chamber but this failed to localise any suspicious area. At this point, based on the ultrasonic study, two 10-0 nylon interrupted sutures were placed through the sclera parallel to the limbus in the suspicious area. These bites were moderately deep in an attempt to engage the internal flap of the cataract wound.

Two weeks postoperatively, the pressure normalised (IOP 12 mm Hg), maculopathy was reversed, and visual acuity improved to 20/50.

Hypotonic maculopathy is an unusual and, to our knowledge, the first reported complication of this kind after pneumatic retinopexy. We hypothesise that the original cataract wound did not heal properly and the additional cryoprobe manipulation caused the following.

Hypotonic maculopathy

Figure 2 UBM picture of right eye showing the external part of the dehiscence cataract wound, as a narrow slit, before repair (area between arrows). There is a full blown hypotonic maculopathy in this eye, with VA 20/200.

Figure 2 UBM picture of right eye showing the same area after repair. Note that the external part of the wound is totally closed (area between arrows) while internal wound gap appears to be more pronounced postoperatively. However, at this point the leak is rectified. IOP and macula are normal with VA of 20/50.
A 26 year old man complained of gradual and painless diminution of vision in both eyes, right more than left, for the past 2–3 years. In view of the history of electrical injury and classic location and typical appearance of the lens opacities, a diagnosis of bilateral electric cataract was made. Extracapsular cataract extraction (ECCE) with posterior chamber intraocular lens implantation was undertaken in both eyes, right eye first followed 3 months later in left eye. The intraoperative and postoperative course were uneventful and the patient has achieved corrected visual acuity of 20/20 in both eyes.

COMMENT
Involvement of the lens exclusively, sparing other ocular structures is rare. This case documents such a possibility and also highlights the salient features involving electric trauma to the lens. The scalp burn in this case represents the entrance wound for the electrical energy but the lack of an exit wound makes this case particularly peculiar. Both entry and exit sites for the electric current have been reported by all previous authors.

The excellent surgical results noted in both eyes of this patient are in keeping with the similar result reported by Portello et al.

This observation should encourage the ophthalmologist to undertake surgery for electric cataract, where necessary, without any undue concern.

**Bilateral electrical cataract**

**EDITOR,—Electric trauma is not uncommon in India where majority of the population lives in the rural setting. Few cases of electric cataract have been reported in literature probably because few patients survive the high voltage of current that induces cataract formation. Most patients with electric cataract have no subjective complaints early on but become aware of the reducing visual function several months later.**

We examined a 39 year old man previously in our clinic because he had experienced hard exudates, and retinal swelling, all of them more prominent in the temporal perimacular area. Fluorescein angiography clearly showed the vascular abnormalities (Fig 1). The left eye fundus was normal. A diagnosis of juxtafoveal retinal telangiectasis was made.

COMMENT
Juxtafoveal telangiectasis is difficult to detect ophthalmoscopically and therefore can be neglected by routine eye fundus examinations made before the first visual symptoms appear. Unilateral renal agenesis occurs in approximately 1 per 1000 births and can be associated with vascular anomalies.

The aetiology of juxtafoveal telangiectasis is unknown. The patient we examined had retinal vascular malformations that may have originated in the early stages of life. Indeed, the deformed capillaries may function for many years before endothelial decompensation causes retinal swelling. While the exact mechanism of Poland's syndrome is not well known, it has been postulated that the original cause may be a vascular abnormality at the embryonic stages. The vascular abnormalities, mostly of the diseased hemithorax, were supported in this syndrome and our finding of retinal vascular abnormalities in this patient support this hypothesis.

To our knowledge, this is the first reported case of coexistence of juxtafoveal telangiectasis, renal agenesis, and Poland's syndrome. Although we are not aware of direct evidence reported in the literature indicating any retinal involvement linked to this syndrome, it is plausible that the three anomalies found in this patient may have had common original vascular causative factors. Therefore, we recommend a careful eye fundus examination of patients presenting with this syndrome.

both optic nerves looked normal. Visual acuities were still 6/5 in both eyes and there was no loss of colour vision or visual field. The intraocular pressures had increased to 22 mm Hg in both eyes.

**COMMENT**

Latanoprost is a prostaglandin F₂α analogue which acts by increasing uveoscleral outflow. Side effects include increased iris pigmentation, hypertrichosis and increased eyelash pigmentation, anterior uveitis in patients with complicated glaucoma or those having had previous incisional surgery, and cystoid macular oedema occurring soon after beginning latanoprost in pseudophakic or aphakic eyes.

Ocular hypotony with choroidal effusions and facial rash have also been attributed to latanoprost.

To the best of our knowledge, optic disc oedema associated with latanoprost has not previously been described. The mechanism behind this association is unclear. One may not be surprised to see optic nerve swelling in association with signs of posterior uveitis or hypotony but in this case it occurred without any sign of ocular inflammation and the lowest recorded intraocular pressure was 15 mm Hg. It may be feasible that the perfusion to the optic nerve heads via the short posterior ciliary arteries was compromised by a prostaglandin-like action manifesting as disc oedema. However, that latanoprost acid and prostaglandin F₂α at high concentrations could cause vasoconstriction of bovine ciliary arteries and a similar action cannot be discounted in this case. The rapid resolution of the swelling with seemingly no long term sequelae once latanoprost was stopped would perhaps support this hypothesis.

**Somatostatin scan positive gastrinoma ocular metastasis**

**EDITOR—**Symptomatic ocular metastases are uncommon despite the 4% prevalence in patients dying of all types of malignancy in postmortem series. We report a case of ocular metastasis from a gastrinoma, which was part of the Wermer’s syndrome (multiple endocrine neoplasia (MEN) type 1), diagnosed by indium labelled octreotide scanning.

**CASE REPORT**

A 57 year old man presented with a 1 week history of blurring in his peripheral vision in his right eye and severe loss of visual acuity, worse early morning. He had been diagnosed with MEN type 1, 8 years previously after two perforated jejunal ulcers (1978, 1990) led to a diagnosis of Zollinger–Ellison syndrome, and a hyperplastic parathyroid gland had been removed for hypercalcaemia (1990). His mother had MEN type 1.

Ophthalmic examination revealed 6/12 acuity in the right eye and 6/5 in the left. His anterior segments were unremarkable. His right fundus showed a solid amelanotic lesion about one disc diameter above the right disc. Ultrasonography demonstrated a base of 13 mm and a height of 8 mm. He also had bilateral inferior retinoschisis. One month later the tumour base measured 14.5 mm and the thickness measured 7.9 mm. The posterior edge now practically abutted the optic disc (Fig 1). There was subretinal fluid accumulation.

A liver ultrasound scan showed multiple lesions and a tumour biopsy was composed of small solid islands of polygonal cells with granular cytoplasm, diagnostic of metastatic neuroendocrine carcinoma (immunostaining positive for chromogranin, neuron specific enolase, and NCAM, negative for S-100 and HMBS45 (melanoma markers)). His urinary 5HIAA was marginally raised at 133 pmol/24 hours (normal up to 75), and a fasting intestinal peptide screen, showed a highly elevated gastrin level (on omeprazole 40 mg per day) of 343 pmol/l (normal range 0–40 pmol/l) but normal levels of other polypeptides.

No primary tumour or further metastases were seen using body computed tomograph and magnetic resonance imaging scans and the I-123 MIBG scan (meta-iodobenzyl guanidine) was also negative. An indium (In-111) octreotide scan at 1 and 4 hours +SPECT showed focal areas of increased uptake in the right orbit (Fig 2), the nasal region, mediastinum, multiple sites in the liver, and possibly other abdominal sites. However, a positive octreotide scan is not exclusively seen with neuroendocrine tumours, since other tissues have somatostatin receptors. These include high grade lymphoma, some small cell lung cancers, occasional tumours of the breast, and in chronic inflammatory conditions where there is T cell activation including endocrine ophthalmopathy with orbital involvement. Thus, although an absolute positive diagnosis of metastatic gastrinoma cannot be made definitively in the absence of histology, in the context of this clinical case it is highly probable that the choroidal tumour is due to ocular metastasis from gastrinoma.

**COMMENT**

Gastrinoma may occur sporadically or as part of multiple endocrine neoplasia. MEN type 1 is a rare disorder, usually inherited in an autosomal dominant fashion with high penetrance which affects multiple endocrine glands (hyperparathyroid hyperplasia in 80–90%, pancreatic islet tumours in 50%, and pituitary adenomas in 40–50%).

Ocular metastasis from gastrinoma has not previously been reported, although it has been reported in other neuroendocrine tumours—for example, carcinoid. Multiple or metastatic gastrinomas (especially if actively secreting) are best localised by a new radioisotope scan using radioactively labelled somatostatin analogues. Somatostatin is a peptide elaborated by the delta cells of the islets of Langerhans and the hypothalamus. It inhibits the secretion of gastrin by gastric mucosa and many other hormones such as insulin, thyrotropin, and corticotropin. Somatostatin receptors are found on neuroendocrine tumours (80% of gastrinomas) and indium labelled octreotide visualises all somatostatin receptor positive gastrinomas. Our scans revealed somatostatin avid liver metastases. Interestingly, the scan also very clearly confirmed the ocular/orbital disease. Orbital radiotherapy and chemotherapy were recommended.

Retinal neovascularisation in Goltz syndrome (focal dermal hypoplasia)

Editor,—This is the first reported case of Goltz syndrome with documented peripheral retinal non-perfusion with subsequent retinal neovascularisation and vitreous haemorrhage. In the eye this represents solely a mesodermal anomaly described by Goltz et al. and neuroectodermal disturbances, such as coloboma or microphthalmia.

Case Report
Goltz syndrome was diagnosed shortly after birth in a girl with linear lesions of atrophic skin following Blaschkó’s lines on the trunk and symmetrical syndactyly of the third to fourth fingers and second to third toes. Initial ophthalmic screening revealed no ocular anomalies. Dental screening revealed the congenital absence of one deciduous incisor. Screening of the parents, brother, and sister was negative for skin, skeletal, and ocular anomalies. When she was aged 5 years, routine ophthalmic review showed a vision of right eye 6/9 and left eye 6/5, with a minor right myopia.

Age 7 years, she complained of a brief episode of photopsia and floaters in the right eye. Vision was right eye 6/20 and left eye 6/6. Examination revealed a right vitreous haemorrhage, telangiectatic vessels temporal to the macula, and temporal equatorial fibrotic vessels and haemorrhage. Fluorescein angiography showed bilateral peripheral retinal non-perfusion and right temporal neovascularisation (see Figs 1 and 2). This was treated conservatively for 2 years; however, after six bleeds within 3 months indirect retinal photoacoagulation to the areas of non-perfusion was performed with subsequent new vessel regression within weeks.

Comment
Focal dermal hypoplasia is a rare disorder of ectodermal and mesodermal dysplasia originally described by Goltz et al. It is characterised by congenital atrophic skin changes often associated with herniation of the subcutaneous fat; skeletal anomalies, in particular syndactyly, polydactyly, or adactyly as well as scoliosis, kyphosis, spina bifida occulta, rib and vertebral anomalies, and dental anomalies, especially hypodontia.

Ocular anomalies occur in 40% of cases. Coloboma have been reported in one third of cases, then less frequently microphthalmia, strabismus, nystagmus, and ectopia lentis. Other reported ocular anomalies include anophthalmia, corneal clouding, aniridia, heterochromia, and optic atrophy. Rarely ectropion and ptosis may occur as well as lid margin or punctal abnormalities.

Retinal neovascularisation in Goltz syndrome remains to be determined. Most cases are sporadic. It is generally thought to be X linked dominant with lethality in males, like IP; however, 9% of cases are male. These are proposed to be the result of half chromatin mutations. Deletions in the region of the chromosome Xp22 are a suggested site, though these must be differentiated from the deletions seen in microphthalmia with linear skin defects (MLS) and that of microphthalmia, dermal aplasia, and sclerocornea (MIDAS), which are now considered to be distinct entities. The wide variation in severity of expression is thought to be due to mosaicism.

Retinitis scleropena associated with airbag inflation

Editor,—Chorioretinitis scleropena is a severe form of blunt trauma, caused by a high velocity object grazing the globe but not penetrating it. It is a concussion injury, which usually manifests as severe choroidal and retinal rupture associated with haemorrhage but an intact sclera. We report a case of chorioretinitis scleropena resulting from deployment of an airbag in a stationary motor vehicle.

Case Report
A 32 year old pregnant woman was the driver in a car accident in which the airbag failed to deploy at the time of impact but inflated when she returned to sit in the driver’s seat approximately 5 minutes after the accident occurred. The patient was not wearing spectacles and there was no evidence of injury from other sources.

At presentation the visual acuity was hand movements in the left eye and 6/6 in the right eye. Examination revealed evidence of swollen eyelids and marked chemosis and subconjunctival haemorrhages on the left, with no bony injury and a full range of eye movements. Anterior segment examination revealed a clear left cornea and a quiet anterior chamber with a microhyphaema. The lens was clear and there was no evidence of dislocation. There was no angle recession and the intraocular pressure was 15 mm Hg.

Figure 1 Colour fundus photograph of right temporal retina showing perfused retina (photo right) to peripheral non-perfusion (photo left) with fibrotic vessels and neovascular complex in the transition zone. (Inferior dislocation is artefact.)
pressure was recorded at less than 4 mm Hg. Fundal examination revealed evidence of a retinal tear although details were obscured by a diffuse vitreous haemorrhage. An ultrasound examination showed a vitreous haemorrhage and large retinal tear but no evidence of a scleral perforation.

An examination under anaesthesia performed the following day confirmed that there was no scleral rupture and indirect ophthalmoscopy confirmed the findings of diffuse vitreous haemorrhage and a retinal tear.

At the 2 week postoperative clinic visit, visual acuity had improved to 6/18. There was 2+ cells in the anterior chamber and the intraocular pressure was 24 mm Hg. Posterior segment findings were an intragel haemorrhage and retinitis sclopeteria with no evidence of retinal detachment.

Four months later, the best corrected visual acuity was 6/36. The anterior chamber activity had settled; the intraocular pressure was 10 mm Hg, and fundal examination was unchanged. In view of the persistent vitreous haemorrhage the patient was listed for routine vitrectomy in the postpartum period.

COMMENT

Airbags are designed to protect the driver from direct impact from the steering wheel, dashboard, and windshield. They are designed to inflate in 10 ms in response to sudden deceleration and during deployment, the airbag is propelled out of its storage compartment at speeds of more than 100 mph. Following inflation the airbag deflates slowly within seconds.

Facial and ocular injuries associated with airbags have been reported in the literature. Skin abrasions, burns, and eyelid ecchymoses are the most common facial injuries. Reported ocular injuries include orbital fractures, kera-
titis, corneal abrasions, hyphaemmas, angle recession, and lens luxation. In the posterior segment, vitreous and retinal haemor-
rhage, commotio retinae, retinal tears and detachments, and choroidal ruptures have been reported. To our knowledge, this is the first reported case of retinitis scleropetria secondary to airbag inflation.

Although airbags have clearly been shown to reduce serious morbidity and mortality associated with road traffic accidents, they are associated with a number of injuries directly attributable to their inflation. Some of these are serious ocular injuries and it is important for ophthalmologists and others involved with trauma cases to be aware of these complications. A full ophthalmic assessment is mandatory in all cases and this should include indentation ophthalmoscopy. A variety of posterior segment injuries have been reported in the literature but this is the first report of retinitis sclopeteria resulting from airbag deployment.

Specular microscopic findings of corneal deposits in patients with Bietti’s crystalline corneal retinal dystrophy

Editor,—In 1937, Bietti1 first described three cases of tapetoretinal degeneration characterised by yellowish glistening retinal crystals, tapetoretinal degeneration with choroidal sclerosis, and marginal crystalline deposits of the cornea. Although more than 100 cases of crystalline retinopathy have been reported, crystalline deposits of the corneal limbus have been observed in only four out of 52 Japanese patients with crystalline retinopathy. Recently, observation using specular microscopy2 has been reported to be useful in detecting crystalline deposits at the limbus of patients with crystalline corneal retinal dystrophy. Therefore, in this study, we examined four patients with crystalline retinopathy using specular microscopy under a “con-surface” mode, which is used for the observation of the corneal surface, and we detected the deposits at the limbus.

Twelve months after the initial specular microscopic examination, we reinspected the crystalline deposits of two cases. Interestingly, the changes in the locations and forms of the crystalline deposits in the corneal limbus were exposed over time (Fig 1). More crystalline deposits were found in the patients with more advanced retinopathy. It is supposed that corneal deposits and fundus deposits are essentially the same and it is suggested that crystalline retinopathy is caused by systemic abnormality. Although the exact pathogenesis of crystalline deposits is still uncertain, it is possible that destroyed fibroblasts appear to glitter or fibroblasts with crystalline-like de-
