LETTERS TO THE EDITOR

Primary sebaceous carcinoma of the lacrimal gland

EDITOR—Sebaceous carcinoma is a rare primary neoplasm of the lacrimal gland and to the best of our knowledge only five cases have previously been reported. 1 2 Sebaceous carcinoma of the orbit more commonly occurs as secondary invasion from the eyelid but may occur as metastatic spread from elsewhere in the body. We report a case of primary sebaceous carcinoma of the lacrimal gland and discuss the histological diagnosis and management of the disease.

CASE REPORT

A 35 year old woman was referred with a 6 month history of a gradually enlarging palpable mass arising in the left superotemporal orbit and causing painless, and progressive diplopia. On examination she had a palpable, hard, fixed, left superotemporal orbital mass, a non-axial proptosis, and hypoglobus. The eyelids were normal. Examination of ocular motility revealed a restriction of left elevation. In addition, she was found to have an enlarged, painless ipsilateral preauricular lymph node. Computed tomograph (CT) and magnetic resonance imaging (MRI) scans showed the mass was arising from the lacrimal gland (Fig 1).

A transseptal biopsy of the mass was performed and histological examination showed tissue infiltrated by carcinoma in which the neoplastic cells were large and contained prominent nucleoli. Many cells were vacuolated and contained lipid as confirmed by fat stains on unprocessed, fixed material. Immunohistochemistry revealed strongly positive staining for epithelial membrane antigen (EMA) but negative staining with anti-cytokeratin, indicating the carcinoma to be of sebaceous origin (Fig 2). Metastatic spread from another primary site was excluded by general physical examination, chest x ray, mammography, and isotopic bone scan undertaken by an oncologist.

A left orbital exenteration with left superficial parotidectomy and excision of left cervical lymph node was performed. Histological examination of the excision specimen showed a 35 × 30 × 18 mm tumour arising in the region of the lacrimal gland, which had been entirely replaced by sebaceous carcinoma, with only a small focus of ductal tissue being present at the margin of the tumour at one point. There was no involvement of the overlying periorbital skin, eyelid, or conjunctiva. The preauricular lymph node contained metastatic deposits, although her cervical lymph nodes were free from metastatic disease.

Postoperatively she underwent radiotherapy to the involved area and the orbit was allowed to granulate and re-epithelialise. Nine months after the surgery an isolated soft, mobile node was noted in the neck. This increased in size over 2 months and was found to be recurrent metastatic carcinoma on fine needle aspiration biopsy. Radical dissection of nodes in the neck confirmed involvement of 30–40 nodes and the patient received further radiotherapy. Six months after this, a swelling in the parotid region without lymphadenopathy again showed recurrent tumour. This lesion responded well to radiotherapy alone. Since then she has achieved good cosmesis with an orbital prosthesis and at the time of writing 3 years after original diagnosis she remains well with no signs of residual tumour.

COMMENT

Primary sebaceous carcinoma of the lacrimal gland possibly arising from heterotopic sebaceous tissue is extremely rare and must be differentiated from secondary invasion of the orbit by a primary eyelid tumour or metastatic spread from other areas of the body. The tumour is highly malignant and metastases to the preauricular and deep cervical lymph nodes occur early in the disease. Orbital exenteration is required and in addition parotidectomy and cervical lymphadenectomy combined with postoperative radiotherapy should be considered as part of the management. The prognosis in previously reported patients was poor with local recurrences and metastases leading to death within 1 year. One previous patient survived to 22 months postoperatively. 3 At the time of writing our patient is the first to show 3 year survival without evidence of further recurrence.

CONGENITAL CIRCUMSCRIBED CHOROIDAL HEMANGIOMA ASSOCIATED WITH INFANTILE HEPATIC HEMANGIOENDOTHELIOMATOSIS

EDITOR,—Choroidal haemangiomas are vascular hamartomas that occur in two distinct forms, circumscripted and isolated, or diffuse, as seen in the Sturge-Weber syndrome. Similarly, hepatic haemangioendotheliomas are benign hamartomatous tumours composed of anastomosing vascular channels lined with endothelial cells. Infantile haemangioendotheliomas (IHE) of the liver are congenital lesions noted at birth or during the first 6 months of life. Hepatomegaly, congestive heart failure, and haemangiomatis of the skin combine to form the classic symptomatic triad. To our knowledge, this is the first report of a congenital circumscribed choroidal haemangioma associated with the first noted association of a circumscribed choroidal haemangioma with a visceral neoplasm.

CASE REPORT

A 3.75 kg male with an uncomplicated prenatal history was born at full term by normal spontaneous vaginal delivery. At birth, the patient was noted to have a single 1 cm diameter cutaneous haemangioendothelioma of his left upper arm. There was no family history of ocular diseases or any haemangiomatous syndromes. The patient’s early postnatal course was complicated by hepatic and congestive heart failure. During this time, his cutaneous haemangioendotheliomas had increased in number ranging from 2 mm to 1 cm in diameter involving his right upper extremity, occiput, and chest wall. An ophthalmological examination was requested to exclude an association of LCHAD (long chain 3-hydroxyacyl coenzyme A dehydrogenase) deficiency, a disorder of mitochondrial fatty acid β-oxidation, which is associated with choroidal and retinal haemangiomas. Funduscopic examination revealed pigmentary mottling of his left macula and a doubled foveal reflex bilaterally. The optic discs and vasculature were within normal limits. A diagnosis of LCHAD deficiency was not supported by further serological testing. Diagnostic imaging revealed multiple hepatic lesions associated with hepatomegaly. Subsequently, at 7 weeks of age a liver biopsy was performed which confirmed the diagnosis of common benign haemangioendotheliomas of the liver. Owing to progressive hepatic and congestive heart failure the patient underwent a living related liver transplantation at 6 months of age. His posttransplant course was otherwise unremarkable with normal growth and development and resolution of his cutaneous haemangioendotheliomas.

Through ophthalmological examination at 7 months of age the patient was able to fix and follow objects bilaterally without evidence of amblyopia. Funduscopic examination, however, revealed bilateral macular pigment epithelial granularity and mottling, greater in his left eye. Re-examination at 10 months of age demonstrated persistent macular pigmentary changes in the left eye with elevation of the macula. Examination under anaesthesia was subsequently performed at 11 months of age which revealed normal anterior segment and clear crystalline lenses bilaterally. Funduscopic examination showed normal discs, vessels, and retinal periphery in both eyes. The right macula was normal without pigmentary abnormalities but the left macula revealed a raised choroidal lesion with an orange coloration and reactive pigmentary changes without retinal, detachment or subretinal fluid. On A and B-scan ultrasonography the maximum height of the lesion was 2.1 mm and the reflectivity of the lesion was high. The clinical and ultrasonographic appearance was most consistent with the diagnosis of a circumscribed choroidal haemangioma. Given the patient’s normal visual acuity and absence of subretinal fluid, observation was recommended in lieu of laser or radiation therapy. Follow-up examination at 15 months of age revealed normal visual acuities without progression of the lesion.

COMMENT

The pathogenesis of haemangiomas remains largely unknown. Histologically, the hepatic and cutaneous haemangioendotheliomas are composed of vascular channels lined by endothelial cells as well as cells suggestive of pericytes. Similar histological characteristics are shared by circumscribed choroidal haemangiomas which consist of a mixture of small (capillary) or large (cavernous) vascular channels lined by flat endothelial cells separated by connective tissue. It has been proposed that persistent arteriovenous shunts, which normally occur in great numbers during the embryogenesis of the choroidal vasculature and then regress, may play a part in the development of choroidal haemangiomas. Whether a similar model may apply in the development of hepatic and cutaneous haemangioendotheliomas remains speculative. Infantile hepatic and cutaneous haemangioendotheliomas show a high incidence of spontaneous regression and therapeutic measures are recommended only when associated conditions lead to morbidity. Although our patient’s hepatic and cutaneous involvement required surgical intervention the natural history of these lesions combined with the patient’s normal vision and lack of associated vision threatening complications justified observation. Should the choroidal lesion eventually give rise to subretinal fluid, macular detachment, and/or decreased visual acuity the patient may benefit from photocoagulation or radiation therapy. Thus, albeit rare and usually diagnosed in adolescence, circumscribed choroidal haemangiomas may present in a congenital fashion and may also be associated with visceral abnormalities of vasoculogenesis.

Echographic localisation of corticosteroid after retrobulbar injection

EDITOR,—Long acting pericocular corticosteroids are commonly used to treat cystoid macular oedema (CMO) resulting from ocular inflammation or cataract surgery that does not respond to topical therapy. Drug localisation to the macular area is considered important for optimal therapeutic effect. In postcataract CMO refractory to topical therapy, corticosteroids delivered by retrobulbar and posterior sub-Tenon’s injections are equally effective. Steroids given by sub-Tenon’s injection have previously been shown to localise to the macular area. Retrobulbar anaesthetic injections have been shown to localise in the intrascleral space, but not precisely to the macular area. We performed ultrasonography after retrobulbar steroid injection to confirm drug localisation in the macular area.

CASE REPORT

Sixteen patients with chronic CMO secondary to sarcoid, idiopathic uveitis, or cataract surgery (Irvin-Gass syndrome) were included in the study. The main inclusion criteria were presence of a visually significant form of CMO that had either failed topical anti-inflammatory treatment, or was deemed clinically severe enough to warrant systemic or periorcular injections of corticosteroids primarily, and willingness to sign informed consent. The main exclusion criteria was refusal to consent to the procedure.

Each eye was injected with 1–2 ml of 40 mg/ml triamcinolone acetonide mixed with 0.5 ml of 2% lignocaine (local anaesthetic) with adrenaline (epinephrine) using a sharp 1½ inch 25 gauge needle. The needle was inserted at the inferotemporal aspect of the lower lid aiming in the direction of the orbital apex. The patient was asked to look straight ahead while the globe was balloted towards the superor orbit with the index finger of the non-injecting hand. Once the needle was positioned in the muscle cone near the posterior pole, the solution was slowly injected. B-mode ultrasound was performed within 30 minutes of the retrobulbar injection. After topical proparacaine (proparacaine) was given, a methylcellulose coupling agent was placed on the ultrasound transducer surface. The coupling agent was directly applied to the ocular surface. Standard longitudinal, vertical transverse, and axial planes were imaged (Figs 1 and 2).

In 15 of 16 (94%) eyes the steroid was visualised in the macular area defined as the portion of the posterior pole bounded by the optic nerve, major temporal arcades, and 3 mm temporal to the fovea. In eyes where the bolus localised to the macular area, the mean distance between the most anterior aspect of...
Early wound dehiscence with use of hydroxyapatite orbital implant covered with calf pericardium

EYTON,—Enucleation techniques continue to evolve. While sclera covered hydroxyapatite orbital implants have been quite effective, two major limitations have led us to study other covering materials. One, while there has been no documented human immunodeficiency virus transmission, several patients have expressed concerns about the use of allogeneic sclera because of that issue. Two, in some settings obtaining cadaver donor tissue in a timely manner can be vexing.

Processed calf pericardium has been used in a number of clinical settings as diverse as vascular grafts and neurological surgical patches. Animal ophthalmic data with these materials have shown little untoward effect. While theoretic concerns about prion disease can be raised no evidence of this problem has been reported from over 90,000 human implantations. While this material is a xenograft that is stored in glutaraldehyde, we are unaware of significant ophthalmic reactions on the basis of either parameter.

I performed a phase I-II trial with commercially available calf pericardium in 14 patients who underwent enucleations for large intraocular tumours. I compared the results with 126 previous enucleations in similar patients by the same author but with placement of allogeneic scleral wrapped HA implants. When two of these 14 cases developed early, apparently non-infective suture line breakdown (compared with none previously) I stopped the use of this approach.

CASE REPORT
In a phase I-II trial 14 eyes of 14 patients, with large intraocular tumours that were not amenable to eye salvage techniques, underwent enucleations in the treatment of CMO. Retrolubbar injection is a procedure familiar to most ophthalmologists, and the decision to perform either a sub-Tenon's or a retrobulbar injection should take into consideration the degree of comfort the administering physician has with the technique.

COMMENT
Depot steroids are an important therapy for treating CMO which is unresponsive to topical therapy. Drug localisation to the macula is considered to be important in maximising therapeutic effect. Steroid therapy delivered by sub-Tenon’s and retrobulbar injections is equally effective, and steroids given by sub-Tenon’s injection have been localised to the macula previously. The localisation of retrobulbar injections to the macular area may explain the similar efficacy of retrobulbar injections to the macular localisation of anesthetic fluid in sub-Tenon’s, peribulbar, and retrobulbar techniques. The second case had recurrent breakdown 2 weeks after enucleation, we removed the anterior face of the calf pericardium that covered the HA implant, and the overlying conjunctival defect was closed with a dural graft. The first patient has done well. The second case had recurrent breakdown anteriorly so that we removed the implant. No pathogenic organisms were seen.

In the historic control group (126 cases), who had scleral covered HA implants, I had no cases with this type of complication in the first 6 months after surgery.
Wegener’s granulomatosis as a cause of cicatrising conjunctivitis

EDITOR—Wegener’s granulomatosis is a multisystem disorder characterised by the classic triad of necrotising granulomas in the upper respiratory tract and the lung, a variable degree of systemic small vessel vasculitis, and a focal necrotising glomerulonephritis. A limited form of Wegener’s granulomatosis, with absence of glomerulonephritis, has been described.1

Ophthalmic complications occur in about 30% of patients with biopsy proved disease.2 Among these orbital pseudotumours ulcerations of the sclera and the cornea are observed most frequently and the histopathological findings have been described.3 Involvement of the conjunctiva and eyelids has also been observed,4 but progressive scarring of the conjunctiva and its sequelae has not been reported.

CASE REPORT
A 72 year old man was first seen at our department in November 1997 with bilateral conjunctivitis. His medical history had been unrevealing until early 1987, when he developed systemic illness with upper respiratory complaints and renal insufficiency. Wegener’s granulomatosis was diagnosed by biopsy of the nasal mucosa and kidney. In 1993 he was referred again in March 1999 after he had suffered several episodes of superficial corneal ulceration in the left eye. On examination the left upper lid was less inflamed than 2 years earlier, but progressive scarring of the tarsus with cicatricial entropion and trichiasis had occurred (Fig 1B). The right upper eyelid showed marked inflammatory thickening, clinically imposing as multiple chalazia. A biopsy from the lateral right upper tarsus disclosed a chronic infiltra- tion with lymphocytes, plasma cells, and occa- sional histiocytes. Numerous eosinophils but no giant cells were noted. Perivascular inflam- mation (Fig 2) and areas of active necrosis were only seen in few areas while disorganisa- tion of the tarsus by fibrous tissue was obvious. Together with the analysis of extrac- tural tissue and the clinical background, the conjunctival biopsy was regarded as diagnostic.

COMMENT
The current state of knowledge has not recog- nised Wegener’s granulomatosis as a disorder causing cicatrising conjunctivitis.1 The diagnosis of granulomatous conjunctivitis in Wegener’s granulomatosis can easily be established in the presence of a history of systemic disease. Conjunctival and eyelid findings, however, may be the presenting symptoms and correct diagnosis is difficult. cANCA levels, a chest x ray film, and an urinary sediment may be helpful in such situations.

Owing to the small number of cases, the experience in treating conjunctival Wegener’s disease is limited. In the absence of detectable cANCA levels or extracellular disease activity, we did initially not recommend systemic treatment with steroids and/or immunosuppressive agents. Considering the progressive course with severe lid complications this approach has to be redefined. Further reports will help in this decision.

An unusual presentation of diabetic neuropathy

EDITOR—Diabetic neuropathy can present in numerous forms; as symmetrical sensory polyneuropathy, mononeuropathy, or as an autonomic neuropathy. The earliest functional change in diabetic nerves is delayed conduc- tion velocity, the earliest histological change is segmental demyelination due to damage of Schwann cells. We report an uncommon but important presentation, which can easily be overlooked on clinical examination.

CASE REPORT
A 27 year old woman was referred to Moorfields Eye Hospital complaining of bilateral corneal erosions. She had a reduced blink rate and peripheral corneal thinning. Her visual acuity was recorded at 6/60 right, 6/24 left unaided. It was also noted that she had complete corneal anaesthesia in both eyes. Basic neurological examination was otherwise normal.

On examination she was noted to have bilateral corneal erosions. Together with the reduced blink rate and peripheral corneal thinning. Her visual acuity was recorded at 6/60 right, 6/24 left unaided. It was also noted that she had complete corneal anaesthesia in both eyes. Basic neurological examination was otherwise normal.

The patient had the typical appearances of a neurotrophic epithelium. She was started on hypromellose 1% eye drops and chloram- phenicol 1% eye drops four times a day, both preservative free to stabilise her epithelium, and this improved her symptoms and vision. Further progress was obtained with therapeutic contact lenses, and her visual acuity improved to 6/18 in both eyes. Because of her
Corneal anaesthesia can be physiological or pathological. Corneal sensation decreases with age, and is lower in females, especially premenstrually. Contact lens wear, and infection by viruses and acute herpes simplex, oedema and surgery will also reduce sensation. Congenital causes of corneal anaesthesia include congenital corneal dystrophy and Riley-Day syndrome, and congenital corneal anaesthesia without an associated syndrome, which is presumed to be due to hypoplasia of the ophthalmic division of the trigeminal nerve. Systemic disease such as diabetes, myotonic dystrophy, scleroderma, and vitamin deficiencies are important causes of corneal anaesthesia, which can often be overlooked. Forty five per cent of diabetic patients had a degree of corneal hypoesthesia when examined in a study of 130 patients published by Osman et al. There is little or no relation between the age of a diabetic patient and the observed decrease in corneal sensitivity. However, corneal sensitivity thresholds do rise immediately on the duration of diabetes.

It has been suggested that diabetic peripheral neuropathy was due to occlusive vascular disease and nerve infarctions. More recent evidence suggests that common symmetrical distal polyneuropathy is due to segmental demyelination with associated or secondary axonal degeneration.

Recent studies show that there may be a potential to use topical neurotrophic growth factors for the treatment of neurotrophic corneal ulceration. In a study of 14 eyes Lambiasi et al treated neurotrophic corneal ulcers with topical nerve growth factor for 2 weeks. Corneal healing began within 2–14 days and all patients had complete healing of their ulcers after 10 days to 6 weeks.

Corneal anaesthesia may often be overlooked unless it is profound. It can be tested with cotton wisp or an anesthesiometer. It is important to test the corneal sensation subjectively and objectively and also to test all four quadrants of the cornea.

This case raises three important points:

- Chronically and irritable eyes should have their corneal sensation tested. Corneal anaesthesia is easily overlooked by non-ophthalmologists and ophthalmologists alike, and the anaesthetic cornea represents a real risk of profound visual loss from trauma and infection.
- Reduced corneal sensation can be a presenting feature of diabetic neuropathy. This woman had no other symptoms or signs of neuropathy apart from her corneal anaesthesia. If a diabetic develops a red or irritable eye, corneal sensation should be tested.
- There is some promise for the future in that neurotrophic corneal ulceration may potentially be treated by the use of topical neurotrophic growth factors.

Corneal anaesthesia may often be overlooked by non-ophthalmologists and ophthalmologists alike, and the anaesthetic cornea represents a real risk of profound visual loss from trauma and infection. If a diabetic develops a red or irritable eye, corneal sensation should be tested.

There is some promise for the future in that neurotrophic corneal ulceration may potentially be treated by the use of topical neurotrophic growth factors. The research into this project continues and is currently not in clinical practice.

Bilateral acute retinal necrosis and herpes simplex type 2 encephalitis in a neonate

EDITOR,—Acute retinal necrosis (ARN) is a rapidly progressing, sometimes devastating, retinitis associated with the herpes virus family. First described in 1971,1 it is diagnosed by the clinical triad of progressive peripheral retinal necrosis, occlusive vasculopathy, and vitreous inflammation.2 The association of herpetic encephalitis with ARN has been described in adults.3 4 Herpes simplex virus type 2 (HSV-2) has also been recognised as one of the causative agents of the ARN syndrome, particularly in Japan.5 It has been suggested that ARN in patients less than 25 years of age is likely to be caused by HSV-2.6 We present a case of bilateral ARN (BARN) in a neonate with HSV-2 encephalitis.

CASE REPORT

A 25 day old infant presented with a 4 day history of lethargy, poor feeding, and coughing. Examination revealed an injected, blistered pharynx and a solitary red skin lesion on the left upper arm accompanied by a cluster of blisters. A clinical diagnosis of possible viral encephalitis was made, and intravenous aciclovir and cefotaxime were commenced. Computed tomography of the brain showed an area of necrotic parenchyma in the thalamus. A scrape from the skin lesion and a sample of cerebrospinal fluid (CSF), obtained by lumbar puncture, were sent for polymerase chain reaction (PCR) analysis. Both specimens were positive for HSV-2. HSV-2 was also isolated in tissue culture from a throat swab. Two days later a bilateral retinitis affecting the superior retina in the right eye and the superonasal retina in the left was identified. A small area of retinal detachment subsequently developed outside the vascular arcades superiorly in the right eye. While in the left eye, an extensive superior retinal detachment occurred, threatening the macula; in the right eye indirect argon laser photocoagulation was used to demarcate the interface between necrotic and healthy retina (Fig 1). In the left, laser was not applied because of the proximity of subretinal fluid to the macula. After 4 days the retinitis was inactive in both eyes; however, a week later the right retina became necrotic prior to the original laser treatment and further indirect laser was applied. In the left eye massive subretinal haemorrhage involving the macula developed and the child underwent pars plana vitrectomy with silicone oil tamponade.

COMMENT

Neonatal HSV infection is usually symptomatic and has a high mortality. Three quarters of cases are due to HSV-2 and this is most commonly acquired from the maternal genital tract lesion during delivery.7 The maternal HSV titres in this case suggest that the mother acquired a primary infection during the third trimester. A diagnosis of encephalitis was confirmed by the CT scan appearance and a PCR positive for HSV-2 in the CSF. The retinitis was first observed only 6 days after the onset of the systemic symptoms and progressed significantly despite intravenous administration of aciclovir. This treatment was continued for several weeks and was then followed by oral therapy. The fact that HSV was not identified from the vitreous or retinal biopsy may be attributable to the prolonged antiviral treatment.8

HSV encephalitis is a severe infection, especially in the neonate, that carries a potential risk of significant ocular involvement. This case highlights the importance of early diagnosis and active management. Like ARN in adults, this may include the need for prophylactic laser retinal photocoagulation to prevent retinal detachment9 and, should this fail, pars plana vitrectomy with silicone oil tamponade.10

EDITOR,—Conjunctival and corneal intraepithelial neoplasia. Surgical excision, autolimbal transplantation. Topical cytotoxic agents have been used successfully in the treatment of CIN.3 However, inhibition of limbic stem cell division with mitomycin C is thought to notably impair physiological corneal epithelial replacement.4 We report the successful use of prolonged mitomycin C after autolimbal transplantation in the treatment of recurrent CIN.

CASE REPORT
A 37 year old white woman presented in February 1995 with a 6 month history of a fleshy white lesion in the corner of her right eye. In the past she had experienced intermittent episodes of bilateral sore, red eyes. Her visual acuities were 6/18 with pinhole in the right eye and 6/5 in the left eye. Ocular examination revealed a whitish elevated lesion on the right limbal conjunctiva from 7 to 11 o’clock extending almost to the central cornea (Fig 1A).

The patient underwent excision biopsy of the lesion. Intraoperatively the exposed bed of the lesion was treated with absolute alcohol and the conjunctival edge with two cycles of cryotherapy. Postoperatively, a bandage contact lens was inserted and she was treated with topical preservative-free antibiotics and steroids. One month later the corneal and conjunctival epithelium had healed completely and vision improved to 6/12. Histology confirmed the lesion to be conjunctival and corneal intraepithelial neoplasia (Fig 1B).

Two months postoperatively, she developed a recurrence in the form of two central, abnormal areas of corneal epithelium. These were treated by scraping and application of absolute alcohol to the bed of the lesion. Histology identified these lesions to be severely dysplastic corneal epithelial cells. Subsequently she developed right limbic stem cell failure resulting in recurrent episodes of filamentary and punctate keratitis and a reduction of visual acuity to 6/18. Histology of corneal scrapes showed epithelial cells and goblet cells. In February 1998 she underwent a right autologous limbal transplant and vision improved to 6/9.

Two months later she had a recurrence of CIN involving one third of the cornea (Fig 1C). This was treated with four cycles of 0.04% mitomycin C applied four times a day, for 10 days at a time. The tumour regressed completely in 3 months. Twenty months later she remains asymptomatic with a clear cornea (Fig 1D).

COMMENT
Mitomycin C is a cytotoxic alkylating agent which inhibits DNA synthesis and is, therefore, most effective against rapidly dividing cells. While it has been used to treat recurrences of CIN, there have been concerns about the effects of mitomycin C on the limbic stem cells and the integrity of the corneal epithelium.5 In our patient the grafted limbal stem cells and corneal epithelium remained healthy in spite of the significant dose of mitomycin C required to treat her recurrent CIN.

To the best of our knowledge this is the first reported case of topical mitomycin C used successfully against CIN after autolimbal transplant, despite the prolonged duration of application (40 days).

The authors would like to thank Miss April Powell-Richards and Professor J Lowry for their help with the illustrations.

Bilateral granulomatous uveitis in association with common variable immunodeficiency

EDITOR,—We report a case of bilateral granulomatous uveitis, which prompted extensive diagnostic review in a 20 year old woman with a long history of recurrent infection and idiopathic thrombocytopenia. Investigations allowed the definitive diagnosis of common variable immunodeficiency with granulomas (granulomatous antibody deficiency syndrome).6 To our knowledge this is the first reported case of granulomatous uveitis in...
association with granulomatous antibody deficiency (GAD). We discuss the features of GAD, and how it may be distinguished from sarcoidosis.

CASE REPORT
A 20 year old woman presented with sudden onset blurred vision. Examination revealed a bilateral granulomatous uveitis withon fat keratic precipitates and anterior chamber cells. Two weeks later she developed bilateral optic disc swelling with multifocal areas of choroidal pallor in her left eye (Fig 1). There was no vitritis or evidence of retinal vascular changes. Her uveitis settled on topical steroids and she maintained vision of 6/6 in the right eye and 6/9 in the left. The working diagnosis was sarcoidosis.

However, serum angiotensin converting enzyme (ACE) was not elevated and magnetic resonance imaging (MRI) showed no evidence of neurosarcoid. Plain chest films and high resolution computed tomography of the thorax revealed bilateral hilar and paratracheal lymphadenopathy, with air space shadowing and ill defined nodular opacities in both lower zones. Bronchial biopsies, obtained at fibre-optic bronchoscopy, showed inflammation of the bronchial epithelium consistent with bronchial pneumonia. No granulomata were seen.

As a child she had suffered from recurrent chest infections, with severe neutropenia and thrombocytopenia. By 6 years of age she had developed splenomegaly and widespread lymph node enlargement. Kveim and Mantoux test were both negative. Investigations for lymphoma over several years were negative. At 13 she underwent splenectomy for idiopathic thrombocytopenia. No definitive diagnosis was established for her in childhood.

She suffered an episode of parotitis and then, at 18, infective discitis of the lumbar spine requiring intravenous antibiotics. This precipitated a drug induced hepatitis with ascites, which became infected, resulting in a chronic, low grade peritonitis. Epstein-Barr virus, cytomegalovirus, and parvovirus serology was normal. Histological review showed that the spleen had little white pulp and few germinal centres (Fig 2), while lymph nodes showed multiple, small, non-caseating granulomata and few germinal centres (Fig 2). Immunological investigation showed all immunoglobulin levels were reduced, with IgG 0.1 g/l (normal 5.4–16.1 g/l), IgA <0.1 g/l (normal 0.8–2.8 g/l), and IgM 1.0 g/l (normal 0.5–1.9 g/l). Lymphocyte subclasses and bone marrow biopsy were normal.

The diagnosis of common variable immunodeficiency syndrome (CVIS) with granulomas was made. Her exacerbations of idiopathic thrombocytopenia responded to immunoglobulin therapy.

Figure 1 Composite fundal photograph showing optic disc swelling and multifocal areas of choroidal pallor, representing granulomata.

Figure 2 (Left) Lymph node showing multiple, small, non-caseating granulomata (haematoxylin and eosin, ×125). (Right) Spleen showing little white pulp and few germinal centres (haematoxylin and eosin, ×125).

as the liver, lungs, spleen, and lymph nodes. This variant is called granulomatous antibody deficiency (GAD): A sarcoid-like syndrome may be seen in 7.5% of patients.

To our knowledge this is the first reported case of bilateral granulomatous uveitis in association with GAD. As in sarcoidosis, serum ACE may be elevated if the granuloma burden is high and a Kveim test may be positive. The diagnosis of GAD hinges on the presence of hypogammaglobulinaemia, while in sarcoidosis immunoglobulin levels are normal or raised.

Granulomatous uveitis is often an indicator of systemic disease. When there is a history of recurrent infection or of autoimmune disease, immunoglobulin levels should be measured to exclude the possibility of a treatable immunodeficiency.

COMMENT
CVIS is a primary immunodeficiency characterised by decreased or absent levels of immunoglobulins. Patients suffer from recurrent bacterial infections and respiratory failure is the principal cause of death. Autoimmune disease is seen in approximately 10% of cases, especially thrombocytopenia, haemolytic anaemia, and rheumatoid arthritis; 25% have splenomegaly and approximately one third have non-caseating granulomata in sites such as the liver, lungs, spleen, and lymph nodes. This variant is called granulomatous antibody deficiency (GAD): A sarcoid-like syndrome may be seen in 7.5% of patients.

A postoperative complication far worse than endophthalmitis: the coexistence of orbital cellulitis

EDITOR,—The coexistence of endophthalmitis and orbital cellulitis in one individual is often a result of endogenous complications, such as metastatic septicaemia or infiltration from a neighbouring orbital infection. However, the coexistence of both these diseases as complications following intraocular or extraocular surgery is very rarely recognised and has only been reported previously in two patients who underwent radial keratotomy and penetrating keratoplasty. We report a patient who underwent uncomplicated phacoemulsification surgery under sub-Tenon anaesthesia and presented with an acute endophthalmitis and orbital cellulitis, leading to phthisis bulbi despite a good response to prompt treatment.
practised and periocular tissues are not draped. We recommend fastidious preparation of the lids and conjunctiva with 5% povidone iodine before sub-Tenon anaesthesia together with appropriate draping in addition to the standard procedure before intraocular surgery which has been shown to reduce the incidence of postoperative infection.

There is a general assumption that orbital cellulitis is an infective consequence of endophthalmitis, where the orbit was infected with the causative pathogen. On the other hand, orbital cellulitis could simply be an inflammatory response to the severe infection of the globe. The patient we describe presented with coexisting orbital cellulitis and endophthalmitis, probably resulting from simultaneous inoculation of the infecting organism into orbital tissues and the eye from the conjunctiva. This is supported by the findings of peri-orbital soft tissue swelling on the CT scan. In addition, the degree of orbital involvement could simply reflect the virulence of the particular organism, which built within 2 months of the initial infection was also the result of the reported case of post-radial keratotomy, even though the causative pathogen differed from the present case. As the prognosis of both coexisting conditions is far worse than endophthalmitis or orbital cellulitis alone, early recognition and the initiation of aggressive treatment are vital.

Figure 1 Patient presented with acute endophthalmitis following uncomplicated phacoemulsification surgery of the right eye, and was noted to have coexisting orbital cellulitis.

CASE REPORT
A 77 year old woman with high myopia and left aphasis underwent uncomplicated elective phacoemulsification surgery of the right eye under sub-Tenon anaesthesia, without intraocular lens implantation. Postoperative ocular examination was satisfactory but on the second day after surgery, she developed headache, vomiting, and ocular pain, with decreased vision in the operated eye to hand movements.

Examination revealed a proptotic right eye with erythematous lid swelling, purulent discharge, and restricted restriction in all extraocular movements. There were generalised corneal oedema, severe fibrinous uveitis, and vitritis. Postoperative endophthalmitis with orbital cellulitis was diagnosed (Fig 1). The patient was admitted for emergency aseptic and vitreous biopsy with intravitreal antibiotic injection. Oral prednisolone 40 mg once daily and standard intensive topical antibiotics were commenced and changed accordingly when bacteriology cultures confirmed the growth of Streptococcus pneumoniae.

She suffered from bronchial asthma with a history of aspirin sensitivity and experienced asthma attacks, conjunctivitis and rhinitis with all extraocular movements. There were generalised corneal oedema, severe fibrinous uveitis, and vitritis. Postoperative endophthalmitis with orbital cellulitis was diagnosed (Fig 1). The patient was admitted for emergency aseptic and vitreous biopsy with intravitreal antibiotic injection. Oral prednisolone 40 mg once daily and standard intensive topical antibiotics were commenced and changed accordingly when bacteriology cultures confirmed the growth of Streptococcus pneumoniae.

COMMENT
The cause of postoperative endophthalmitis is often a result of inoculation of pathogens directly into the ocular cavity during surgery or indirectly into periocular tissues with subsequent access gained via an open wound. However, the precise mechanism leading to orbital cellulitis from endophthalmitis is less clear.

In our patient, sub-Tenon anaesthesia was applied and this could potentially have served as an access for the pathogen into the orbital cavity. One of two reported cases of postoperative endophthalmitis and orbital cellulitis received only topical anaesthesia at the primary procedure; orbital cellulitis developed following vitreous biopsy and intravitreal antibiotic injection, and the type of anaesthesia was not mentioned. Sub-Tenon anaesthesia is an increasingly popular procedure for intraocular surgery, and when performed by the anaesthetist, skin preparation is usually undertaken using Betadine (Seton), but conjunctival lavage with antiseptic is not usually undertaken.

Second Sight
Second Sight, a UK based charity whose aims are to eliminate the backlog of cataract blind in India by the year 2020 and to establish strong links between Indian and British ophthalmologists, will be sending volunteer surgeons to India early in 2001. Details can be found at the charity website at www.secondsight.org.uk or by contacting Dr Lucy Mathen (email address lucymathen@yahoo.com).

14th Annual Meeting of German Ophthalmic Surgeons
The 14th Annual Meeting of German Ophthalmic Surgeons will be held at the Marien-Inn, Nuremberg, Germany on 17–20 May 2001.
