Ultrasound biomicroscopic study of sclerotomy sites after implantation of sustained release drug devices

S Kunimatsu, Y Fujino, Y Nagata, K Ono, M Mochizuki, J Numaga, H Kawashima, M Arai

Background/aims: To evaluate the potential of ultrasound biomicroscopy (UBM) as a tool to study the precise location and changes of sclerotomy sites of the eye with an intraocular drug delivery device.

Methods: Eight eyes of six patients (13 sites) who received ganciclovir implants were examined by UBM. Examinations were performed 1–26 months (mean 12.8 months) postoperatively. Serial transverse and radial sections of the anterior ciliary body around the sclerotomy sites were obtained.

Results: The ganciclovir implant contour was successfully viewed using an UBM with high reflectivity. Three implants were deviated anteriorly and they were very close to the ciliary body and the lens (anterior deviation), while four implants were deviated posteriorly and away from the lens (posterior deviation). The other six implants were located at the appropriate position as intended. A solitary homogeneous mass with a medium reflectivity around the suture tab was observed at 12 out of 13 sites in seven eyes. Thick membranes extending from sclerotomy sites to the ora serrata were found at two sites in two eyes. Conclusion: UBM is helpful in detecting abnormal manifestations around ganciclovir implants and is a valuable tool to assess the changes of the sclerotomy sites of the sustained released intraocular devices.

RESULTS

The ganciclovir implant contour was successfully viewed using an UBM with high reflectivity. Typical UBM pattern of the implant is shown in Figure 1. A transverse section showed the anterior surface of the implant of high reflectivity away from the eye. This technique has made it possible to observe anatomical alterations of tumours in the anterior segment, the ocular angle, and glaucoma. UBM can be used not only for the anterior chamber observation, but also for the observation of ciliary body cysts, non-pigmented ciliary epithelial detachments, and sclerotomy sites after pars plana vitrectomy.

Although histopathological studies have been performed on the enucleated eyes treated with ganciclovir implants, no in vivo studies are available to demonstrate the precise location and changes of the sclerotomy sites in eyes treated with sustained release ganciclovir implants. This study demonstrated for the first time the usefulness of UBM to examine and monitor the site of intraocular ganciclovir implants in patients with cytomegalovirus retinitis.

MATERIALS AND METHODS

Sixteen sustained release ganciclovir implants (Vitransert, Chiron Vision Co, Claremont, CA, USA) were installed in eight eyes of six patients (one implant in three eyes, two implants in two eyes, and three implants in three eyes). The first implant was placed in the inferotemporal quadrant; if the implant was inserted twice or more in the same eye, the second implant was placed in the inferonasal quadrant, and the third implant was placed after removing the first implant in the inferotemporal quadrant. Thirteen of these 16 implants (13 sites) were subjected to the current study.

We followed the surgical procedure described by Martin and associates. Briefly, a conjunctival peritomy was constructed in the inferotemporal or inferonasal quadrant, then a 5–6 mm pars plana incision was created 4 mm from the limbus, and prolapsed vitreous was removed using an automated vitrectomy device. A ganciclovir implant was inserted into the vitreous cavity with special attention being paid not to touch the lens surface, and sewn into place with an 8-0 Nylon suture. The wound was closed with running 8-0 Nylon sutures.

The sites were examined by UBM (model 840; Humphrey Research Division, San Leandro, CA, USA) using a 50 MHz transducer. UBM examinations were performed 1–26 months (mean 12.8 months) postoperatively. After topical anaesthesia (oxybuprocaine hydrochloride 0.4%, Benoxil, Santen Pharmaceutical Co, Osaka, Japan), an eyecup containing hydroxyethyl cellulose (Scopisol, Senju Pharmaceutical Co, Osaka, Japan) and physiological saline was applied. Serial transverse and radial sections of the anterior ciliary body around the sclerotomy sites were obtained by UBM. One examiner (SK) performed all the examinations.

RESULTS

The ganciclovir implant contour was successfully viewed using an UBM with high reflectivity. Typical UBM pattern of the implant is shown in Figure 1. A transverse section showed the anterior surface of the implant of high reflectivity away.
from ciliary processes. A radial section showed the anterior surface of the implant found in transverse section.

UBM examinations made it possible to identify the location of the implant in the vitreous and the deviation of the implant from the appropriate position. Of the 13 sites examined, three implants were deviated anteriorly and they were very close to the ciliary body and the lens (anterior deviation) (Fig 2A), while four implants were deviated posteriorly and away from the lens (posterior deviation) (Fig 2B). The other six implants were located at the appropriate position as intended. A solitary homogeneous mass with a medium reflectivity around the suture tag was observed at 12 out of 13 sites in seven eyes. Thick membranes extending from the sclerotomy sites to the ora serrata were found at two sites out of 13 sites in two eyes. A summary of the results is shown in Table 1.

**DISCUSSION**

The present study clearly demonstrated that UBM made it possible to record the sustained release drug devices that were implanted in the vitreous cavity. UBM is a newly developed technique using a high-resolution ultrasound. Because of the high resolution, the exact position of the implant in the vitreous cavity and post-surgical changes of the vitreous near the device were clearly demonstrated.

Although all 13 implants were inserted into the centre of the vitreous cavity, three implants were deviated anteriorly and four implants were deviated posteriorly. A solitary homogeneous mass around the suture tag and thick membranes extending from the sclerotomy sites were also observed. These findings cannot be detected by slit lamp biomicroscopy.

The treatment of various ocular diseases is hindered by poor penetration of topically or systemically administered drugs into the eye. For example, in the case of corticosteroids, topical application is not effective in the treatment of intermediate or posterior uveitis because of poor permeability into the vitreous cavity. After systemic administration, there exist at least two major barriers that lie in the tight junctions of retinal pigmented epithelial cells and retinal capillaries. Furthermore, extended systemic use of corticosteroids could well induce numerous unwanted side effects. To overcome the disadvantages of these drug delivery routes, intraocular sustained drug delivery systems were sought.

Ocular complications such as vitreous haemorrhage and retinal detachment, have been reported after ganciclovir implantation. These complications occur more often after exchange procedures when the implant is depleted of the drug. The exact causes of the complications are not known, yet information about the precise locations of the implants,
any abnormal manifestations around them, and the sclerotomy sites are essential to understand the cause. Histologically, Charles and Steiner found that the implant was supported by fibrous tissue that emerges from a surgical coloboma of the pars plana ciliaris in four eyes of three patients. Morley et al. also found a fibrous sheath encasing the strut and the suture during the ganciclovir exchange, which made extraction of the implant more difficult. Although no necropsy or histological study has been performed in the patients in the present study, the structural changes—that is, homogeneous masses and thick membranes demonstrated by UBM, are compatible with their findings.

The devices observed in the current study did not develop serious complications. We speculate that structural changes at the site of implantation may be related to vitreous hemorrhages or retinal detachments that have been described previously. Furthermore, the homogeneous masses and thick membranes observed by UBM may be related to complications during and after the exchange operation. More data are needed to clarify the clinical implications of these findings by UBM.

The intraocular drug delivery system may become mainstream in delivering various drugs, such as corticosteroids, cyclosporin, and antibiotics that can yield better concentrations in the vitreous than conventional systemic or topical instillation. A certain proportion of them will be replaced or removed during an extended period of time and surgical complications may occur during or after an exchange operation. On balance, we believe that UBM can become a useful tool for evaluating abnormal manifestations around intraocular drug delivery devices after implantation.
