Laser induced chorioretinal venous anastomosis in ischaemic central retinal vein occlusion

Laser induced chorioretinal venous anastomosis (CRVA) has been advocated by McAllister and Constable as a treatment for non-ischaemic central retinal vein occlusion (CRVO). This technique potentially offers a means of permanently bypassing the site of obstruction to venous outflow, which is thought to occur in the region of the lamina cribrosa. In ischaemic CRVO, the visual prognosis is usually much poorer, with devastating complications like neovascular glaucoma and progressive macular ischaemia. In this prospective study, we investigated the feasibility of laser induced CRVA in eyes with ischaemic CRVO, in view of the possibility of avoiding or lessening these severe complications.

Materials and methods
The classification of ischaemic CRVO was based on the presence of 10 disc diameter or more of capillary non-perfusion in the fundus fluorescein angiography (FFA), according to the criteria in the CRVO study. Approval from the ethics committee and informed consent from patients were obtained. Inclusion and exclusion criteria are shown in Table 1. All the laser treatment was performed by one of the authors (AK) who had successfully treated patients with non-ischaemic CRVO with a similar procedure. The site for attempts at the creation of anastomosis was the inferotemporal and superonasal retina over a venous tributary of the retinal vein where it crosses over an underlying choroidal vein, at least 3 disc diameters away from the optic disc. Argon or diode laser with 50 µm spot size of 0.1–0.2 second’s duration and with a power level of 1.5–2.5 W was focused over the edge of the chosen retinal vein. Increasing power was used until there was haemorrhaging from the vein (Fig 1A). The bleeding was stopped by pressure on the eye with a contact lens.

Results
Six eyes of six patients were included (Table 2). All of them had posterior vitreous detachment. Median follow up was 21 months (range 5–31 months). The median preoperative best corrected visual acuity (BCVA) was 3/200 (range, hand movement to 8/200). The median postoperative best corrected visual acuity (BCVA) was 2/200 (range, hand movement to 20/200). The median number of attempted anastomosis sites per eye was four (range, two to four). Through repeated ophthalmoscopic examination, FFA, and indocyanine green angiography, no functional anastomosis was found. A small nodular fibrotic scar was noted in each site (Fig 1B). No other significant laser related complication was found. One eye eventually developed rubecotic glaucoma.

Comment
In non-ischaemic CRVO, a successful CRVA was created in 33–54% of eyes. Laser photocoagulation treatment parameters differed, because the superiority of one combination of parameters compared with another had not been demonstrated. In our study, it appears that argon or diode laser induced CRVA was not feasible in ischaemic CRVO. We attribute this to the severe endothelial cell damage secondary to ischaemia and venous thrombosis across the retinal circulation. In a dog model without retinal vein occlusion, a successful laser induced CRVA was shown to be lined by endothelial cells. Despite the failure to create functional CRVA, we did not encounter any adverse complication related to the laser treatment. The presence of posterior vitreous detachment in our patients might have lessened the chance of development of chorioretinovitreal neovascularisation. Successful CRVA in ischaemic CRVO has been reported to be established through pars plana vitrectomy with direct surgical puncture or erbium:YAG laser. This surgical approach may be a better option to create CRVA in ischaemic eyes, especially when the posterior hyaloid is still attached preoperatively.

Actinic granuloma of the conjunctiva

Actinic granuloma is a condition characterised, histologically, by a preponderance of giant cells in close relation with damaged elastic fibres and the absence of necrobiosis, lipid, mucin, and palisading of the granuloma. The term was coined in 1975 by O’Brien who described similar histological features in cutaneous lesions of patients with sun damaged skin.1 Actinic elastosis is the hallmark of pingeueulae and has been noted in association with a granulomatous reaction in only one previous report.2

Over the past three decades, three cases of actinic granuloma of the conjunctiva have been documented in the literature (Table 1).4** The paucity of reports ensures that the condition is under-recognised both clinically and pathologically. We describe a further case with the novel association of scleral thinning, and further review the literature with reference to pathogenesis, disease associations, treatment, and significance for both ophthalmologists and pathologists.

Case history

A 67 year old white woman presented to the ophthalmology department with a 3 week history of a painless, red right eye. She had no previous ophthalmic problems. Significant past medical history included treated pulmonary tuberculosis and a mastectomy for breast carcinoma 10 years previously. She had no significant family history and otherwise was generally well.

Ocular examination demonstrated a 3 × 3 mm, raised, flesh coloured, vascularised lesion on the right nasal bulbar conjunctiva with an associated corneal dellen (Fig 1). Further scleral changes were observed circumferentially around the limbus under an apparently healthy conjunctiva (Fig 1, arrowhead).

Initial differential diagnosis was carcinoma in situ of the conjunctiva or metastasis from breast carcinoma, although the lesion was not clinically typical of either.

An excision biopsy was performed. During surgery the underlying sclera was noted to be degenerate with significant thinning.

Histology of the lesion demonstrated dysplasia within the squamous epithelium and prominent solar elastosis with a granulomatous response to degenerative elastic fibres. There was a lymphoplasmacytic infiltrate characteristic of an inflamed pingeueula with granulomatous features suggestive of actinic granuloma (Fig 2).

Investigations into the cause of the underlying scleral atrophy included full blood count, erythrocyte sedimentation rate, serum VDRL, serum complement, anti-ro and anti-la antibodies, and rheumatoid factor which were all within normal limits. A screening serum ANCA was weakly positive (1:20) but anti-myeloperoxidase assays were negative.

Anterior segment ultrasonography was normal. Fluorescein angiography of the anterior segment demonstrated an evenly perfused iris, but a filling defect clearly delineated the atrophy and thinning at the lesion site. Our patient was subsequently treated with topical antibiotics and eye padding and responded favourably over several weeks with progressive epithelialisation over the excision defect (Fig 3). The scleral changes persisted after resolution of the epithelial defect (Fig 3, arrowhead).

Comment

O’Brien, in his original description of actinic granuloma, described the pathogenesis as a phenomenon of repair occurring in damaged connective tissue.® This concept was disputed by Ragaz and Ackerman® who believed that the granulomatous inflammation was not a response to degenerative elastic fibres but...

that the lesions described by O’Brien represented variants of granuloma annulare, a disorder of skin and ocular adnexae.1 The existence of conjunctival actinic granulomas in isolation distinguishes this condition from granuloma annulare and implies that granuloma formation can occur in response to elastic material. Furthermore, actinic granulomas are histologically distinct with prominent elastic degeneration of connective tissue fibres, giant cells, and inconspicuous palisading of epithelioid histiocytes. McGrae postulated that actinic granuloma represented a cell mediated immune response to weakly antigenic determinants on actinic- altered elastotic fibres with a predominance of helper T cells in the lymphocytic infiltrate.1 More recently the association of temporal arteritis and actinic granulomas of the skin has been documented.2 It is hypothesised that actinic radiation selectively injures elastic tissue in the skin and its superficial arteries and this tissue may then become antigenic, with local, humoral, and systemic overtones. It is reported that the serum of patients with untreated giant cell arteritis contains a significantly elevated level of an elastase in the form of matrix metalloproteinase 9 (MMP-9) and that this enzyme was found to be abundant in the vicinity of damaged temporal internal elastic laminae.3 Gillet et al4 observed that sera from 12 of 13 patients with untreated giant cell arteritis contained high levels of elastase derived elastin peptides and that the peptides were targeted by T lymphocytes such as appear in the actual lesions of actinic granulomas. This mode of autoimmune reaction complies with the “danger” model of autoimmunity described by Matzinger and appraised by Larkin.5 Our case presented with the novel association of an underlying focal scleral atrophy. Negative investigations for scleritis would suggest that this feature may be an extension of the autoimmune process representative of actinic granuloma rather than an independent idioopathic scleritis. It is interesting to note that all documented cases of actinic granuloma of the conjunctiva have occurred in females which would be supportive of an autoimmune pathogenesis. Clinically, the differential diagnosis of conjunctival actinic granulomas includes pingueculitis, Bowen's disease, conjunctival naevus, granuloma annulare (pseudorheumatoid nodule), and episceral rheumatoid nodule. Pathologically, the differential diagnosis includes pingueculae, pingueculitis, infection—particularly fungal, parasitic, or mycobacterial—and foreign body reactions. However, there is no granulomatous reaction to the actinic elastosis in pingueculae. In fungo- and parastic lesions there is often a prominent eosinophilic infiltrate associated with the granulomas. Caseous necrosis is seen in mycobacterial infections. In difficult cases special stains may help. Polarised light microscopy rules out the presence of any birefringent material. Actinic granuloma of the conjunctiva represents a distinct clinical, histopathological, and immunological entity. Its classic presentation over a short period of a few weeks and poor response to topical steroid treatment should aid the ophthalmologist in recognising this lesion. Of practical importance to the ophthalmic pathologist is recognition that the granulomatous inflammation may be associated with elastic degeneration and does not necessarily imply the presence of a foreign body, fungal, or mycobacterial infection.

Unilateral nasal hemianopsia secondary to posterior subcapsular cataract

Visual field defects respecting the vertical midline are a common occurrence associated with focal neurological lesions. However, unilateral nasal hemianopsias are rare defects, documented to be associated with pituitary adenomas, temporal optic nerve lesions, and uprasellar aneurysms. Cataracts are known to depress the overall sensitivity of the visual field, but localised visual field defects due to cataract are extremely rare and, to our knowledge, only three other cases have been reported in the literature. We report a case of a right unilateral nasal hemianopsia resulting from central posterior subcapsular lens opacity.

Case report

A 51 year old woman treated for normal tension glaucoma in her right eye for 2 years attended for a review of her glaucoma following a change of medication with the addition of bimonidine eye drops to dorzolamide eye drops. At this 3 monthly review the patient

Figure 1

Humphrey 24-2 visual field showing (A) precataract visual field, (B) field with cataract and visual field defect, (C) visual field after cataract removal.
give a 1 month history of a sudden onset of misty vision affecting her right nasal visual field noticed while driving her car. There were no other associated neurological symptoms. Just before this she had been diagnosed with “borderline” systemic hypertension. There were no other risk factors for a vascular event, although there is a positive family history—her father had had a cerebrovascular accident.

On examination, her visual acuity had dropped from 6/6 to 6/24 in the right eye, remaining unchanged at 6/6 in the left since the previous visit. It had also been documented that letters on the nasal side of the Snellen chart were not seen with the right eye. Confrontation visual field examination demonstrated a nasal hemianopia of the right eye. Her pupils were equal with normal reactions to light and accommodation. Dilated slit lamp biomicroscopy revealed marked central posterior subcapsular lens opacity with very mild subcapsular changes in the other eye, previously documented as normal. Retinal examination was normal and the optic discs pathologically cupped with inferior rim thinning; changes consistent with glaucoma, although there was normal and the optic discs pathologically cupped with inferior rim thinning; changes consistent with glaucoma, although there were no documented changes from the previous visit 6 months earlier.

Further neurological and cardiovascular examination, including a blood pressure of 170/70 mm Hg, were also unremarkable.

The right nasal hemianopia respecting the vertical midline was confirmed on a clinically reliable Humphrey 24–2 plot with a change in mean deviation from −5.94 to −17.43 from the previously documented visual field (see Fig 1). The visual field of the left eye was normal. Routine blood tests and chest x-ray were normal. A computed tomograph (CT) scan of the brain showed no abnormality; visual pathways were also unremarkable. In the absence of a focal neurological lesion this woman subsequently underwent an uncomplicated right phacoemulsification and intraocular lens replacement. A repeat red spot visual field resulted in complete reversal of the previously documented right nasal hemianopia, and a restoration of the visual acuity to 6/6.

Comment
Media opacities are known to cause visual field defects,’ the degree of which varies from generalised depression of the visual field to apparent scotomatous areas. Localised paraxial lens opacities causing defects mimicking neurological abnormalities are extremely rare. These opacities necessitate a posterior position in the lens to produce a relative scotoma. An opacity in the media anteriorly placed produce generalised reduction in the visual field. In the previous three reported cases all the cataracts were posterior subcapsular in nature.

Our case is unusual in that the cataract was placed centrally, not temporally as may be expected with a nasal defect. Further, the history suggested a sudden onset which necessitated neurological examination and investigation.

We feel it would have been inappropriate to proceed to surgical intervention without previous investigation, which should always include a CT scan (more preferably, if readily available, an magnetic resonance imaging (MRI) scan), of the optic nerves and visual pathways. This unusual visual field defect may have been present for some time before the appearance of the cataract but, if subtle, may not have been evident. However, the presence of the cataract may have decreased the sensitivity of the eye and made the visual defect more prominent. Our concern with this woman was that removing the cataract may have disguised a more sinister underlying pathology—that is, a neurological defect, so we decided on a red spot visual field to confirm that such a defect was indeed not present.

Whereas in this case the right nasal hemianopia was due to a posterior subcapsular cataract, we believe that a neurological cause for the field defect should always be sought, particularly with a history of sudden onset. Cataract extraction should be considered only establishing the absence of the same. Further, consider performing a postoperative red spot visual field test to confirm the absence of focal neurology in such eyes.

Lack of human papillomavirus in pterygium of Chinese patients from Taiwan

We read with interest that Gallagher et al had demonstrated the association of human papillomavirus (HPV) and pterygium by polymerase chain reaction (PCR). Several hypotheses concerning the pathogenesis of pterygia have been proposed, including exposure to ultraviolet irradiation and other environmental factors, genetic predisposition, and viral infections. The various theories regarding pterygium formation imply that much about the pathogenesis of pterygia remains to be investigated.

The involvement of HPV in the genesis of pterygia is controversial. Some authors have demonstrated that HPV is present in 24–50% of specimens, whereas others have failed to detect HPV in pterygia.1 To help resolve this dilemma, we evaluated 65 pterygia, 23 pinguecula, and 88 normal conjunctiva derived from Chinese patients in Taiwan for the presence of HPV DNA. We used PCR with three different consensus primer sets—MY09/ MY11 (MY), L1C1/L1C2-1 (LC), and GP5/ GP6 (GP).

Material and methods
Samples were obtained from consecutive patients treated at the ophthalmological clinic of the Taipei Veterans General Hospital. Medical and ophthalmologic histories were recorded for each patient, a slit lamp microscope examination was performed, and pterygia were photographed before surgery. In each case, a specimen of adjacent clinically normal conjunctival tissue (from the 12 o’clock position of the corneconjunctival limbus) was obtained. Immediately after surgery, tissue specimens (pterygia, pingueculae, or conjunctival tissues) were stored at −70°C.

DNA preparation
The DNA from specimens was isolated as described previously. Briefly, the lysis buffer (10 mM TRIS-HCl; pH 7.5, 1 mM EDTA, pH 7.9; 0.5% SDS) and the protease K (100 µg/ml) were added to the specimens and incubated overnight at 37°C. The standard phenol-chloroform extraction and the ethanol precipitation were used for DNA purification and the pelleted DNA was resuspended in 50–100 µl of distilled sterile water. To determine the quality and quantity of the isolated DNA, each pelleted DNA sample was analysed by electrophoresis on 1% agarose gels stained with ethidium bromide and viewed spectrophotometrically.

PCR analysis for HPV
Each amplification reaction was carried out in a total volume of 20 µl overlaid with one drop of mineral oil and contained 10 mM TRIS-HCl (pH 8.3), 50 mM KCl, 0.25 U Taq DNA-polymerase (Perkin-Elmer), and 100–200 ng DNA. The concentration of dNTPs and MgCl2, varied with each set of primers. Each PCR was carried out in DNA thermal cycler (Perkin-Elmer Cetus DNA Thermal Cycler 480) with the first denaturation step at 92°C for 4 minutes and the final extension step at 72°C for 15 minutes. The conditions and the number of denaturation, annealing, and extension cycles were different with each set of primers.

To control the quality of the isolated DNA internally, the 268 bp sequence of β-globulin gene was amplified using PCR (5′-CAGCTCAGCAGTTCA-3′) primers and GH20 (5′GAAGAGCCAAGGACAGG-3′) in the multiplex PCR with the MY, LC, or GP primers. DNA samples extracted from cell cultures infected with HPV were used as a positive control. Each PCR product was analysed by electrophoresis on 2% agarose gels stained with ethidium bromide.

PCR with MY09 and MY11 consensus primers
The PCR with MY09/MY11 was performed as described previously. The PCR mixture was supplemented with 2.5 mM MgCl2, 0.2 mM of each dNTP, 0.5 mM MY09 and MY11 primers (Table 1) and 0.3 μM PC04 and GH20 primers. The DNA amplification was carried out during 40 cycles that included denaturation at 92°C for 30 s, annealing at 53°C for 30 s, and primer extension at 72°C for 30 s.

PCR with L1C1/L1C2-1 consensus primers
The PCR with L1C1/L1C2-1 was performed as described previously. The PCR mixture was supplemented with 4 mM MgCl2, 0.2 mM of each dNTP, 0.5 mM MY09 and MY11 primers (Table 1) and 0.25 μM L1C1 primers (Table 1). The DNA amplification was carried out during 30 cycles that included denaturation at 92°C for 30 s, annealing at 53°C for 30 s, and primer extension at 72°C for 30 s.

PCR with GP5/GP6 consensus primers
The PCR with GP5/GP6 was performed as described previously. The PCR mixture was supplemented with 2.5 mM MgCl2, 0.05 mM of each dNTP, 0.5 mM GP5 and GP6 primers (Table 1) and 0.3 μM PC04 and GH20 primers. The DNA amplification was carried out during 40 cycles that included denaturation at 94°C for 30 s, annealing at 45°C for 30 s, and primer extension at 72°C for 30 s.

Results
The specimens included 65 conjunctiva, 23 pingueculas, and 88 normal conjunctivae. Characteristics of patients are shown in Table 2. We were unable to detect any HPV DNA fragments in the 23 specimens of pingueculae, 65 specimens of pterygia, and 88 specimens of normal conjunctivae tested.

Comment
It has been proved that HPV possesses oncogenic potential and contributes to the development of various preneoplastic and neoplastic conditions. DNA of many types of HPV, particularly types 16 and 18, has been detected in papillomas, dysplasia, and cancers observed on the eyelids, lacrimal outflow tract, conjunctiva, and cornea.3 In this study, three sets of consensus primers, MY, LC, and GP, were used; we were unable to detect HPV in any pterygium, pinguecula, or normal conjunctival specimen from Chinese patients in Taiwan, where the prevalence of pterygia is high.

Three studies have addressed the presence of HPV DNA in pterygia and all used PCR amplification with a single primer (Table 3). These reports demonstrated big differences in frequencies, from 0% to 100%, and variety of HPV types (type 6, 11, 16, 18) that could be possibly explained by the different primers used, the absence of adequate controls, small sample size (10–50 specimens), and possible different frequencies of HPV infection in geographically distinct populations. Confirmatory larger studies in different geographic populations using more efficient primer(s) are needed to clarify the relation between HPV infection and pterygium formation.

The similar controversy occurred in the detection HPV DNA of malignant epithelial neoplasms of conjunctiva but not squamous cell papilloma of conjunctiva.8 By reviewing the published data of previous reports, HPV positive rates in conjunctival papilla specimens were quite consistent, from 44–75% and most of the HPV types were type 6 and 11 that were classified as low risk HPV genotypes.9 But in the case of malignant epithelial neoplasms of conjunctiva, the frequencies of HPV detection varies from 0–100% and both low risk, HPV-6 and HPV-11, and high risk, HPV-16 and HPV-18, groups were found by various molecular techniques.10

Owing to different populations studied and the absence of a gold standard HPV detection technique and adequate controls in most studies published to date,11 there are marked variations in the obtained HPV prevalence rates in pterygium. Therefore, HPV probably does not act alone in the development of pterygium and the exact role of HPV in the pathogenesis of pterygium remains unclear. The lack of HPV DNA in pterygium in this study may indicate either the HPV is not associated with pterygium formation or that the technique was not adequate for demonstration of such an association. Based on our data, we suggest that HPV is not a required cofactor in the development of pterygia.

Grant support: none.

P = primary; R = recurrent.
Factor V Leiden mutation does not correlate with retinal vascular occlusion in white patients with Behçet's disease

The factor V Leiden (FV Leiden) mutation causes resistance to activated protein C by substituting the Glu residue with arginine at the cleavage site for activated protein C. Heterozygous carriers of the FV Leiden mutation have an increased risk of venous thrombosis between threefold and sevenfold in population based and family studies.

Behçet's disease is a chronic inflammatory multisystem disorder that affects young adults. The principal cause of visual loss in this disease is recurrent retinal vein occlusion probably due to a combination of retinal vasculitis and thrombus formation. Thrombosis in Behçet's disease carries a poor ocular and systemic prognosis, so the presence of an identifiable and significant risk factor could be an indicator for anticoagulant treatment.

Two recent studies have implicated FV Leiden in the pathogenesis of thrombosis in Turkish patients with Behçet's disease. In one study, 30% of patients with Behçet's disease complicated by thrombosis were heterozygous or homozygous for factor V Leiden compared to 5.9% of factor V Leiden negative patients. In the second study, factor V Leiden was detected in 37.5% of patients with Behçet's disease and a thrombotic history, compared to 9.4% of non-thrombotic patients. We have previously shown in a study of 106 Middle Eastern patients with Behçet's disease and 120 racially matched controls that the prevalence of factor V Leiden was significantly higher among patients with ocular inflammation (odds ratio 1.67) and was even more prevalent in patients who had developed retinal vascular occlusive disease (odds ratio 1.70).

In this current study we analysed the association between factor V Leiden and clinical features of Behçet's disease in white patients from the United Kingdom. The results show that, unlike Middle Eastern Behçet's disease patients, factor V Leiden was not associated with Behçet's disease in UK patients.

Patients
DNA samples from 53 white patients with Behçet's disease were collected from individuals attending the Behçet's disease clinic at the Medical Eye Unit, St Thomas's Hospital, London. All patients fulfilled the international criteria for Behçet's disease. Middle Eastern and Afro-Caribbean patients were excluded from this study. A total of 150 white controls from the London area were provided from our DNA bank. Patients’ clinical details were recorded following full systemic and ocular examination, the diagnosis of retinal vein occlusion being recorded following fluorescein angiography.

Factor V Leiden analysis
HLA typing and detection of the FV Leiden mutation was performed using PCR-SSP as previously described. The results were analysed by generating two by two contingency tables and statistical analysis was performed using χ² test.

Results
Fifty three patients (28 males, 25 female) were analysed; 74% (n=39) had ocular disease, 11 had no ocular disease, and for three patients the ocular disease status was unknown. Of those patients with ocular disease, 54% (21/39) had retinal vein occlusion.

Twenty two of 33 (64%) were HLA-B*51* of whom 3/22 (14%) were B*5108, the remainder being B*5101 (Table 1).

Only 2/53 (3.8%) patients in this cohort of patients with Behçet’s disease were heterozygous for the FV Leiden mutation (Table 1). Both patients were male, and had ocular disease, however only one of these individuals had evidence of retinal occlusion.

Comment
The factor V Leiden mutation has been linked with ocular disease in Middle Eastern patients with Behçet’s disease, in particular those with proved retinal venous thrombosis. The current data on UK patients with Behçet’s disease do not show a similar association. The prevalence of FV Leiden in the patient group was no different from the control group. Moreover, while both patients positive for FV Leiden had ocular disease this is against a background of a high level of eye disease in this group.

There are several possibilities that could explain the difference between the two groups. Firstly, the presence of FV Leiden in the Middle Eastern population was particularly high (17%) and this may have accounted for the functional role of this molecule in retinal venous thrombosis in this group. By comparison, the low prevalence of the mutation in white people suggests that much larger numbers of Behçet’s disease patients will need to be tested to identify any possible association. This has been supported by studies on other European patients with Behçet’s disease where FV Leiden was not identified as a risk factor for systemic venous thrombosis.

Moreover, in our previous study, we identified several patients who were homozygous for FV Leiden mutation and were clinically blind. In a population with such a high prevalence of the mutation, homozygosity will be more common and may have biased the data in favour of an association between FV Leiden and severity of ocular disease in the patient group.

Secondly, recent studies in relatives of individuals with venous thrombosis have shown that the presence of FV Leiden adds only a threefold risk of thromboembolism. Over half of these events were linked to other risk factors such as pregnancy, surgery, or oral contraceptives. This would suggest that in the general white population genetic mutations affecting proteins involved in the coagulation cascade might only be associated with thrombosis in individuals with concurrent risk factors.

Thirdly, population specific phenotypic effects have been described for other gene polymorphisms. In a worldwide survey of HIV+ and HIV− individuals, a particular haplotype of the RANTES gene was associated with increased risk of acquiring HIV-1, and accelerated disease progression, in European Americans, but not African-Americans. A second RANTES haplotype was associated with delayed progression of disease in Japanese

patients, but not in other ethnic groups of patients, probably because this haplotype is rarely found in non-Far East Asians. There are several other factor V gene polymorphisms that may be involved in white patients and these could be an area for future study.

These results suggest that interindividual and interpopulation specific genotypes are associated with disease although the phenotypic outcome remains the same. Therefore gene polymorphisms that associate with disease in one population cannot be regarded as associating with the disease in different ethnic groups. It may not be possible to identify genes involved in severity of a complex disease such as Behcet's disease, which will hold across different patient populations.

Figure 1 Clinical appearance of the lesion on presentation. Note the gelatinous appearance and the marked vascularisation.

Figure 2 Photomicrograph of a Congo red
stained section of the lesion showing amyloid in the corneal stroma.

Localised corneal amyloidosis
associated with herpetic keratitis

Amyloid diseases are secondary protein structure
diseases in which insoluble protein fibrils
accumulate extracellularly. Twenty different
types of fibrils have been described in human amyloidosis, each with a different clinical picture. Amyloidosis can be generalised, affecting multiple organ systems, or localised and can affect almost any organ of the body. In the eye amyloid is the material commonly seen in lat-
tice corneal dystrophy. Cases of localised corneal amyloidosis have been reported in lit-
erature but are quite rare.1–7 We report a case of localised corneal amyloidosis presenting as
a large raised gelatinous vascularised lesion in a patient with long standing herpetic keratitis.

Case report

A fit and healthy 34 year old woman was a ter-
riary referral to the corneal clinic with a long
standing history of a lesion on her right cornea. The initial presentation as a teenager was as a
red sore right eye with a corneal ulcer that was
treated as a bacterial ulcer for a few years and
later on as recurrent herpetic keratoconjunctivitis.
She had had numerous intermittent courses of
treated combined topical antivirals and steroids with
resolution of symptoms. Over the past 2 years she
was noted to develop a raised vascularised
lesion over the right cornea, which gave her a
constant foreign body sensation and occasional
episodes of pain. It was the appearance of
the lesion and the discomfort rather than the
reduced visual acuity, which prompted her to
seek treatment. On presentation in the clinic
she had a visual acuity of 6/36 right (6/24
with pinhole) and 6/6 left eye. Anterior segment
examination showed a large, raised, gelatinous,
slightly nodular, vascularised lesion on the
right cornea (Fig 1). The rest of the anterior
segment examination was normal. Ocular adn-
exae did not show any signs of chronic lid dis-
ease. The corneal sensation was intact. A
superficial keratocyte was performed under
general anaesthesia to excise the lesion. His-
topathological examination of the specimen
revealed a diagnosis of amyloidosis (Fig 2).

Comment

Amyloidosis can be either primary or second-
ary, both of which can be further classified
into systemic and local disease. Systemic pri-
mary amyloidosis can affect various ocular
structures presenting as papules or purpura
on the lids, conjunctival deposits, external
ophthalmoplegia, vitreous opacities, and glau-
coma. Secondary systemic amyloidosis rarely
affects the eye, although a case of conjunctival
amyloidosis has been reported in a patient
with rheumatoid arthritis.1

Staﬀord and Fine, for the ﬁrst time in 1966,
reported a case of corneal amyloidosis in a
young girl with ocular complications of retin-
apathy of prematurity.2 Primary familial amy-
loidosis, which presents as nodular white subepithelial protuberances in the central
cornea, has been postulated to be autosomal recessive.3 In secondary localised corneal
amyloidosis, the material has been postulated as a result of chronic inﬂammation and irritation
from scarred lids from trachoma, trichiasis, or long standing corneal scars.4–7 To the best of
our knowledge its association with herpetic keratitis has not been reported.

Macpherson et al retrospectively examined
200 specimens of corneas removed for various
reasons speciﬁcally for amyloid deposits and
found it present in seven cases (3.5%).1 It has
been proposed that the basal cells of the
epithelium are responsible for the synthesis of amyloid, although other sources have
been also proposed.1

Bilateral macular staphylomas in a patient with cone dystrophy

A posterior staphyloma is characterised by
scleral ectasia and is pathognomonic for pathological myopia.1,2 Posterior staphylomas
are classified into five types based on the
anatomic location.1 Type 1 staphylomas ex-
tend from the nasal border of the optic nerve
into the macular region and are the most
frequent staphyloma seen in myopes.3 Type 2
staphylomas are centred on the macula while
Type 3 staphylomas are centred on the optic
Figure 1  (A) and (B) Bilateral macular staphylomas in a patient with cone dystrophy. There are macular retinal pigment epithelial changes consistent with cone dystrophy. The retinal vessels in both eyes appear to dive posteriorly into staphylomas that are centred around the macula (type 2 staphylopa).

disc without macular extension. Type 4 staphylomas are located nasal to the optic disc and type 5 staphylomas develop inferior to the optic disc.

This report describes a patient with undiagnosed, bilateral type 2 macular staphylomas compounded by cone dystrophy. To the best of our knowledge, this is a novel association not reported in the literature and with potential therapeutic implications.

Case report

A 32 year old white woman presented to the Wilmer Ophthalmological Institute, Baltimore, MD, for a second opinion. She reported having progressively worsening vision since childhood and was diagnosed with cone-rod dystrophy at age 18 by an outside opthalmologist. She experienced photophobia both indoors and outdoors. She denied recent changes in her vision. Past ocular history was otherwise significant for a remote history of corneal abrasion in the right eye. Past medical history and family history were non-contributory.

On ophthalmological examination, her uncorrected visual acuity was 20/200-2 in the right eye and 20/200-1 in the left eye. Retinoscopic reflex and refraction were variable and significant for mild myopia. Refraction did not improve her vision. There was no relative afferent pupillary defect and extraocular movements were normal. There was no evidence of nystagmus. Slit lamp biomicroscopy of the anterior segment was unremarkable. Dilated fundus examination showed a tilted optic nerve head in each eye. There were bilateral macular retinal pigment epithelial changes consisting of a ring of hypopigmentation surrounding an area of mildly increased pigmentation centrally (Fig 1). The retinal vessels in each eye appeared to dive into posterior staphylomas (Fig 1). The staphylomas were centred around the macula in each eye. The peripheral retina in each eye was otherwise normal.

Fluorescein angiography demonstrated mottled hyperfluorescence without leakage corresponding to the retinal pigment epithelium (RPE) changes (data not shown). Goldmann visual fields were remarkable for central scotomas in both eyes with peripheral isoptres full to II-4 stimulus in the right eye and I-4 stimulus in the left eye (Fig 2). A B-scan showed bilateral staphylomas with macular involvement (Fig 3). On electroretinography, photopic responses were markedly reduced. The dim scotopic responses were normal. The mixed scotopic responses were 90% of normal in the right eye and 97% of normal in the left eye. There were markedly reduced photopic flash and flicker responses, with a questionable response of 10% of the normal amplitude. Pelli-Robson contrast sensitivity testing was depressed at 1.2 log units in a dim environment (normal = 1.65). D15 colour testing detected four major and three minor errors in the right eye, and five major and two minor errors in the left eye. A therapeutic red tinted contact lens was prescribed to eliminate the photophobia and aversion to light due to cone dystrophy, and thereby to reduce the level of visual dysfunction. After 1 month of wear, the patient reported being a lot more comfortable in bright surroundings. She did not have to squint as much as before using these lenses, was able to sustain prolonged eye contact with other individuals, had improved face recognition and demonstrated improved posture. Visual acuity was 20/125 in each eye tested separately and 20/80-2 when both eyes were tested together.

Comment

In summary, we have described a patient whose findings are consistent with a diagnosis of cone dystrophy compounded by bilateral macular staphylomas. We believe that this does not represent congenital achromatopsia given the absence of nyctagmus and the history of progressively worsening vision. Although there is a report of familial cone dystrophy with bilateral macular colobomata, we are unaware of a case of bilateral macular staphylomas associated with cone dystrophy. To our knowledge, this case represents a previously unreported association of cone dystrophy with macular staphylomas. Awareness of this association will hopefully contribute to proper diagnosis as this finding had presumably been missed in previous ophthalmological examinations.
Given the significant association of macular staphylomas with numerous complications listed above, especially the risk for choroidal neovascularisation and haemorrhage, such patients should receive counselling regarding its symptoms and receive periodic comprehensive ophthalmological examinations.

Bloody tears, or haemolacria, are an occasional feature of hereditary haemorrhagic telangiectasia, and tumours of the lacrimal apparatus. In the emergency department, however, they are more commonly encountered accompanying epistaxis. To date, Medline lists only one single case report of haemolacria in this context, and the photograph presented here may well be the first of the phenomenon.

Its anatomical basis lies in the intimate connection of nose and eye via the lacrimal apparatus. An increase in pressure within the nasal cavity during epistaxis—for example, by pinching or blowing the nose, can cause retrograde flow of blood through the system and thus lead to bloody tears emerging from the ipsilateral eye.

As our patient had longstanding perforation of both tympanic membranes, the blood in her nose was also able to travel retrograde via the auditory tube and middle ear into the external auditory canal. This led to the additional bleeding from the right ear.

Bleeding was readily controlled by nasal sponge tamponade. The patient made an uneventful recovery.

Haemorrhagic toxoplasmosplastic retinochoroiditis: description of an unusual clinical presentation

Toxoplastic retinochoroiditis (TRC) is an infectious disease caused by the protozoan Toxoplasma gondii. This infection affects many organs including the eyes. Most of the time ocular involvement occurs after a transplacental transmission, throughout pregnancy, but the infection can also be acquired. In immunocompetent patients, TRC is the most common cause of infection affecting the posterior segment. Clinically, the lesion appears as a white foci necrosis involving the full thickness of the retina, at the margin of an old pigmented chorioretinal scar. A vitreous inflammation is usually present and occasionally vascularity is observed.

We report the case of a healthy patient who developed a unilateral haemorrhagic retinochoroiditis (RC). The investigations performed were positive for a TRC.

Case report
A 43 year old African man was referred with a 10 day history of a painless progressive visual loss affecting the left eye. No other ophthalmological or systemic complaints were present. His past medical history was unremarkable.

Ophthalmological examination disclosed a vision of 20/20 in the right eye without correction and in the left eye the best visual acuity was 20/200. Anterior segment examination was normal in the right eye but revealed a mild inflammation in the left.

Intraocular pressure was within the normal limits in both eyes. Left eye fundus examination showed a vitreous inflammation (cells: + +++) and a whitish retinochoroidal lesion surrounded by a large preretalinal haemorrhage. Hard exudates were present in the macular area as well as a retinal oedema (Fig 1).

Investigations revealed an erythrocyte sedimentation rate of 6 mm in the first hour (reference range 1–12), and a normal white blood cell count. Serological testing for toxoplasmosis gave negative results for IgM but IgG titres were 40 IU/ml (reference range >3). Serology tests for Borrelia burgdorferi, Treponema pallidum, and HIV were normal. An acute infection was suspected and we decided to perform an anterior chamber tap. Polymerase chain reaction (PCR) (toxoplasmosis, CMV, HSV, VZV) gave negative results, but the Goldmann-Witmer coefficient was 13:64 (reference range <4), revealing a local production of anti-toxoplastic immunoglobulins. Tests for sarcoidosis and for connective tissue disorders were negative. Immunoglobulin electrophoresis, quantitative immunoglobulin levels, CD4-CD8 lymphocyte count, C3-C4 and CH50 examination were within the normal range. PPD skin test was just positive (7 mm). Chest x ray was normal.

Based on these findings, a TRC was diagnosed. The patient was treated with sulphadiazine (4 × 1 g/day), pyrimethamine (2 × 25 mg/day) and folic acid, during 6 weeks. Topical steroids and mydriatic drops were prescribed. Prednisone (1 mg/kg) was introduced, at tapering doses, during the treatment.

After 3 months, visual acuity returned to 20/20 without a correction in the left eye. Anterior segment examination was normal. Left eye posterior segment examination disclosed a regression of the haemorrhages and a white chorioretinal scar with hard exudates located around the fovea. Kyrieleis’s plaque were observed along the inferior papillary arterial vessel (Fig 2).

The patient was followed during 2 years and no reactivation of the RC was observed. Moreover, tests to exclude an immune disease were still within the normal limits (HIV, immunoglobulin electrophoresis, quantitative immunoglobulin levels, PPD skin test, CD4-CD8 lymphocyte counts, C3-C4, and CH50).

Comment
The most classic clinical presentation of an active toxoplastic lesion is that of a whitish and oedematous necrotising RC close to an old pigmented scar. A severe vitreous inflammation or a large preretalinal haemorrhage. Hard exudates are observed in the macular area.

Figure 1
Figure 1
Bloody tears, and more! An unusual case of epistaxis

A 56 year old woman presented to the emergency department with a 2 hour history of bleeding from the right nostril. She had tried to stop it by pinching her nose but had then also experienced bleeding from her right eye and ear (Fig 1).

Figure 1
Right sided haemolacra and bloody otorrhoea in the context of epistaxis. Photograph reproduced with the consent of the patient.

Figure 1
Fundus of the left eye. Presence of an oedematous retinochoroidal lesion surrounded by a large preretalinal haemorrhage. Hard exudates are observed in the macular area.
inflammatory reaction is usually associated, appearing as a “headlight in the fog.” Lesions can occur anywhere in the posterior segment but most of the time, they are located in the macular area, affecting one or both eyes. Associated findings include the presence of an inflammatory sheathing of retinal vessels. However, a variety of clinical presentations have been reported in the past; Friedmann et al described the presence grey-white fine punctuate lesions affecting the deep retina with a mild vitreous inflammation. Direct optic nerve involvement by the protozoan was described by Zimmermann in 1956. More recently, various clinical aspects of TCR were described in immunocompromised hosts, appearing as diffuse areas of retinal necrosis or as a bilateral military retinitis. Ocular occlusive vasculitis can be observed in inflammatory diseases including Behget’s syndrome, sarcoidosis and systemic lupus erythematosus, in infectious disorders (sphingitis, acute retinal necrosis), and in TCR. Branch artery obstruction has been reported when a vessel passes through an acute TCR, as well as retinal vein occlusion. The case reported here was diagnostically challenging as the fundus appearance was not characteristic of classic TCR. In fact, haemorrhages are more frequently found in viral infections such as cytomegalovirus retinitis. This feature could be explained by damage to the vascular wall passing through the RC, without signs of a vascular obstruction. This case demonstrates the importance of including toxoplasmosis in the differential diagnosis of unilateral haemorrhagic RC in immunocompetent patients.

Topical dorzolamide and metabolic acidosis in a neonate

We describe a neonate with bilateral Peter’s anomaly who became unwell and developed a metabolic acidosis after commencing topical dorzolamide. He was fully investigated to exclude other causes of acidosis, and subsequently improved on discontinuation of topical treatment. To the best of our knowledge, there have been no reports of topical carbonic anhydrase inhibitors causing metabolic acidosis in children or adults.

A 5 day old boy was referred to a tertiary ophthalmic centre with bilateral Peter’s anomaly. He had been noted to be unwell at 48 hours of life, with feeding intolerance and purpura. He was referred to the neonatal unit at 4 days of age for metabolic investigations and correction of metabolic acidosis. The baby was noted to be extremely irritable, pale and dehydrated. A harlequin configuration was noted, and there was marked mottling of the scalp. A full history was taken, which included no history of maternal rubella, varicella or chickenpox, and the baby was not at risk of congenital toxoplasmosis.

Ocular examination revealed total left upper lid ptosis, left strabismus, and total right upper and lower lid ptosis. Bilateral hypertelorism was noted with prominent eyes. The left eye had more severe ptosis and strabismus than the right eye. A very small left eye was noted which was unable to track, with no light perception present. The right eye had normal ocular movement with 20/20 vision. An anterior chamber aspiration was performed to consider diagnosis of congenital glaucoma. Intravenous cefotaxime, flucloxacillin, half correction bicarbonate infusion followed by oral sodium bicarbonate supplements for 3 days. He showed some improvement with treatment; however, he remained significantly acidic and unwell. At routine ophthalmic review 5 days later, while free of all other treatments, the eye drops were stopped and he showed spontaneous next-day resolution of his acidosis. He symptomatically improved and gained weight over the subsequent few days (Fig 1).

Topical dorzolamide has been shown to cause significant reduction in intraocular pressure (IOP) in children and is well tolerated. Secondary glaucoma is well recognised in cases of Peter’s anomaly and raised IOP is well known to cause corneal clouding. Congenital corneal opacities necessitate urgent treatment in order to reduce amblyopia, and therefore it is essential to exclude glaucoma. Topical Trusopt (MSD) is used routinely at the department of ophthalmology, Great Ormond Street, as it is thought to have lower potential for adverse systemic effects than topical β blockers.

Topical dorzolamide is a potent inhibitor of CA-II and this inhibition decreases the rate of aqueous humour secretion consequently lowering IOP. In the proximal renal tubule CA-II is also required to sustain maximal rates of HCO3 reabsorption. Significant systemic inhibition of carbonic anhydrase has not been observed and there has been an absence of demonstrable metabolic effects in adults. However, with the oral carbonic anhydrase inhibitor, acetazolamide, the renal carbonic anhydrase involvement and acidosis have been shown to be proportionally related to the plasma concentration levels of the drug. The dose per kg systemic absorption of topically

![Figure 1](http://bjo.bmj.com) Trend in metabolic acidosis over time.

![Figure 2](http://bjo.bmj.com) Fundus of the left eye (3 months after treatment). Regression of the haemorrhages. Presence of a whitish retinochoroidal scar with hard exudates around the fovea. Kyrieleis’s plaques are observed along the inferior papillary arterial vessel.
administered dorzolamide would be expected to be higher in neonates/infants of lower body weight compared with adults. Metabolic acidosis with normal anion gap and serum electrolytes in the absence of diarrhoea, as in this case, is more likely to be due to proximal renal tubular bicarbonate loss. Spontaneous improvement of the acidosis on termination of the topical dorzolamide is strongly suggestive of the culpability of dorzolamide. It is unclear as to why this happened, but factors such as prematurity, low birth weight, renal tubular immaturity, and one functioning kidney may have led to poor handling of drug elimination at a higher systemic concentration. Although we feel dorzolamide is a relatively safe topically hypertensive treatment, this case underlines the need for caution when treating neonates.

Recurrent infectious crystalline keratopathy caused by different organisms in two successive corneal grafts in the same patient

Infectious crystalline keratopathy (ICK) is a rare complication of penetrating keratoplasty characterised by an indolent infectious keratitis in which needle-like, branching crystalline opacities are seen within the corneal stroma, in the absence of appreciable corneal or anterior segment inflammation.1 We report an unusual case of recurrent ICK which occurred in two successive corneal grafts.

Case report

A 63 year old man underwent penetrating keratoplasty for aphakic bullous keratopathy. The immediate postoperative course was uneventful. Topical corticosteroid (dexamethasone 0.1%) was initially given four times daily, and was tapered to twice daily. Seven months after transplantation, visual acuity decreased to counting fingers with no other symptoms. Slit lamp examination showed a focal area of non-suppurative branching intrastromal white opacities (Fig 1). Corneal scrapings for diagnostic smears and cultures were performed. Microscopic examination of the smears showed dense groupings of many Gram positive cocci with no inflammatory cells. Cultures grew Streptococcus viridans and were negative for fungi. The patient was treated hourly with two fortified antibiotic eyedrops (amikacin, vancomycin) and topical rifamicyn. Topical antibiotic therapy was gradually tapered over 12 months. Topical dexamethasone was withdrawn and topical ciclosporin was used to maintain an immunosuppression. Despite intensive treatment with appropriate antibiotics, ICK increased in size and evolved simultaneously towards abscess and acute rejection. The subsequent corneal condition was severe residual scarring of the central cornea with diffuse neovascularisation. A second penetrating keratoplasty was then performed 19 months after the first transplantation. Topical dexamethasone, ciclosporin, and rifamicyn were given four times daily. Three months after the second graft, slit lamp examination showed a large central epithelial defect with multiple diffuse white opacities confined to the anterior stroma. These multiple opacities merged into a larger confluent dense opacity near the continuous suture (Fig 2). Cytological studies and cultures of the corneal scrapings were performed. Light microscopy disclosed aggregations of many fungi with no inflammatory cells. Cultures yielded Candida albicans sensitive to amphotericin B and fluconazole. Bacterial cultures were negative. Topical amphotericin B was started every hour, along with oral fluconazole. Corticosteroids were stopped and topical ciclosporin was maintained. Despite intensive treatment, the infectious keratopathy slowly worsened over 6 months and the corneal infiltrates were replaced by scarring and neovascularisation.

Comment

Typically, ICK develops in a corneal graft after long term use of topical corticosteroids. Chronic topical corticosteroids used to prevent graft rejection produces relative immunosuppression allowing infection to develop with little or no inflammation in the cornea. Gram positive cocci, usually Streptococcus viridans, are commonly isolated from ICK lesions, but other bacteria, fungi, and mixed infections have been reported.2 To the best of our knowledge, recurrent ICK has never been reported in two successive corneal grafts and with two different organisms. Appropriate laboratory evaluation is therefore necessary to guide specific antimicrobial therapy. Discontinuation of topical steroids with aggressive antibiotic therapy may suffice, but continued infection, vascularisation, or scar formation may sometimes affect visual acuity and corneal graft survival. In this case, medical treatment failed, despite in vitro susceptibility of micro-organisms to antibiotics and antifungal drugs. Moreover, immunosuppression (that is, corticosteroids, ciclosporin), necessary to prevent graft rejection, worsened the infection and did not prevent the acute rejection process from developing.

In conclusion, this case suggests that local immunosuppression and factors related to the patient ocular surface may be predisposing factors for the development of ICK.

Rosai Dorfman disease or sinus histiocytosis with massive lymphadenopathy of the orbit

Sinus histiocytosis with massive lymphadenopathy (SHML) or Rosai Dorfman syndrome is a rare benign proliferative histiocytic disease of unknown origin. It predominantly affects the lymph nodes. The head and neck region usually in association with lymph node involvement, represents one of the most common extranodal areas affected by SHML. The other common extra nodal site is skin. Rarely, there is widespread dissemination with liver, kidney, respiratory organs, orbit, and eyeball involvement. The mean age of onset is 20 years (birth to 74 years).

Case report

A 57 year old woman with a 6 month history of double vision was referred to the Royal Victoria Eye and Ear Hospital, Dublin. She was found to have proptosis, ptosis, diplopia due to inferior rectus dysfunction, and restriction of elevation of the left eye. Her visual acuity was normal. Relevant investigations showed a high erythrocyte sedimentation rate (ESR) of 44 mm in the first hour, C reactive protein of 1.9 (normal less than 1). Her thyroid function tests, including thyroid microsomal and thyroglobulin antibodies, were normal. The anticyt choline receptor antibodies were also negative. A computed tomogram (CT) scan of the orbit was performed which showed an extracranial soft tissue mass with well defined margins in the inferomedial part of the left orbit and no separation from inferior and medial rectus. There was no bony erosion and the optic nerve appeared normal. She had an excision biopsy performed through lateral orbitotomy with Wright’s modification.

The tumour was removed within the capsule, it was found to be adherent to the inferior and lateral rectus. Histological examination of the tumour revealed an inflammatory process composed of aggregates of lymphocytes, with reactive lymphoid follicles, plasma cells, and groups of large histiocytes with abundant foamy cytoplasm. The inflammatory process extended around the nerves. There was no vasculitis, areas of coagulative necrosis, or granuloma formation. The large histiocytic cells were characterised by rounded to oval, vesicular, hypochromatic nuclei with variable chromatin and abundant eosinophilic, foamy or clear cytoplasm with poorly defined cell borders. Emperipolesis was evident in patients with SHML with their histiocytic cells characterised by round to oval vesicular, hypochromatic nuclei with defined cell borders. Emperipolesis was seen. The phagocytosed cells were most often erythrocytes, lymphocytes, and plasma cells, and in another report the only site of the lesion was lacrimal sac with the duct but these patients later developed cervical lymphadenopathy. Another case with ocular involvement was reported with uveitis and marginal corneal infiltrates in association with cervical lymphadenopathy. SHML is usually benign, low grade, and self limiting but death has been infrequently attributed to it. The condition has also been occasionally associated with the development of malignant lymphoma. Hodgkin’s and the follicular type of non-Hodgkin’s lymphoma and SHML have been identified in the same lymph node biopsy specimen. SHML may be associated with fever, leucocytosis, elevated erythrocyte sedimentation rate, and hypergammaglobulinemia. Some studies suggest that human herpes virus (HHV-6) may play a part in pathogenesis of SHML. HHV-6 which infects many in childhood and remains latent in host cells can be reactivated by immunodeficiency. Serological evidence of HHV-6 and Epstein-Barr virus infection have also been documented in patients with SHML with their presence in affected tissues as well. SHML is usually self limiting but in some cases there was orbital involvement with compressive optic neuropathy, persistent uveitis with marginal corneal infiltrates, massive lymphadenopathy impairing cervical perfusion, and generalised lymphadenopathy with AA amyloidosis. These cases were treated with chemotherapy and oral steroids, the commonest being cyclophosphamide, vincristine, mercaptopurine, and prednisolone. Treatment causes regression of the tumour and resolution of cervical lymphadenopathy with minimal recurrence. Our patient did not receive any treatment and in the 3 year follow up there was no evidence of recurrence of the disease in the orbit or any sign of sinus histiocytosis elsewhere in the body.

Comment

In one report of SHML, uveitis with papilloedema was the only presentation and in another report the only site of the lesion was lacrimal sac with the duct but these patients later developed cervical lymphadenopathy. Another case with ocular involvement was reported with uveitis and marginal corneal infiltrates in association with cervical lymphadenopathy. SHML is usually benign, low grade, and self limiting but death has been infrequently attributed to it. The condition has also been occasionally associated with the development of malignant lymphoma. Hodgkin’s and the follicular type of non-Hodgkin’s lymphoma and SHML have been identified in the same lymph node biopsy specimen. SHML may be associated with fever, leucocytosis, elevated erythrocyte sedimentation rate, and hypergammaglobulinemia. Some studies suggest that human herpes virus (HHV-6) may play a part in pathogenesis of SHML. HHV-6 which infects many in childhood and remains latent in host cells can be reactivated by immunodeficiency. Serological evidence of HHV-6 and Epstein-Barr virus infection have also been documented in patients with SHML with their presence in affected tissues as well. SHML is usually self limiting but in some cases there was orbital involvement with compressive optic neuropathy, persistent uveitis with marginal corneal infiltrates, massive lymphadenopathy impairing cervical perfusion, and generalised lymphadenopathy with AA amyloidosis. These cases were treated with chemotherapy and oral steroids, the commonest being cyclophosphamide, vincristine, mercaptopurine, and prednisolone. Treatment causes regression of the tumour and resolution of cervical lymphadenopathy with minimal recurrence. Our patient did not receive any treatment and in the 3 year follow up there was no evidence of recurrence of the disease in the orbit or any sign of sinus histiocytosis elsewhere in the body.

Figure 1 Sinus histiocytosis. A lymphoid infiltrate surrounding scattered large histiocytic cells containing phagocytosed intracytoplasmic lymphocytes (arrows) is seen. Original magnification ×200.

Second Sight
Second Sight, a UK based charity whose aims are to eliminate the backlog of cataract blind in India by the year 2020 and to establish strong links between Indian and British ophthalmologists, is regularly sending volunteer surgeons to India. Details can be found at the charity’s website (www.secondsight.org.uk) or by contacting Dr Lucy Mathen (lucymathen@yahoo.com).

SPecific Eye Conditions (SPECS)
SPecific Eye Conditions (SPECS) is a not for profit organisation which acts as an umbrella organisation for support groups of any conditions or syndrome with an integral eye disorder. SPECS represents over 50 different organisations related to eye disorders ranging from those that are relatively common to very rare syndromes. The website acts as a portal giving direct access to support groups own sites. The SPECS web page is a valuable resource for professionals and may also be of interest to people with a visual impairment or who are blind. For further details about SPECS contact: Kay Parkinson, SPECS Development Officer (tel: +44 (0)1803 524238; email: k@eyeconditions.org.uk; website: www.eyeconditions.org.uk).

The British Retinitis Pigmentosa Society
The British Retinitis Pigmentosa Society (BRPS) was formed in 1975 to bring together people with retinitis pigmentosa and their families. The principle aims of BRPS are to raise funds to support the programme of medical research into an eventual cure for this hereditary disease, and through the BRPS welfare service, help members and their families cope with the everyday concerns caused by retinitis pigmentosa. Part of the welfare service is the telephone help line (+44 (0)1280 860 363), which is a useful resource for any queries or worries relating to the problems retinitis pigmentosa can bring. This service is especially valuable for those recently diagnosed with retinitis pigmentosa, and all calls are taken in the strictest confidence. Many people with retinitis pigmentosa have found the Society helpful, providing encouragement, and support through the Help line, the welfare network and the BRPS branches throughout the UK (tel: +44 (0)1280 821 354; email: lynda@brps.demon.co.uk; website: www.brps.demon.co.uk).

Surgical Eye Experiments International
Volunteer ophthalmologists in active surgical practice are needed to participate in short term, sight restoring eye surgery clinics around the world. Rise in organ transplant numbers
According to UK Transplant, the UK has seen the highest number of organ transplants in six years. Last year (1 April 2002 to 31 March 2003) 2777 patients had their lives saved or dramatically improved through the generosity of 1064 donors. This equated to a 6% increase compared to the previous 12 months (1 April 2001 to 31 March 2002). Furthermore during 2002–3, the highest number of people benefited from a cornea transplant for five years (1997–98) and 240 more people had their sight restored than the previous year. For further information see UK Transplant’s website (www.uktransplant.org.uk).

Elimination of avoidable blindness
The 56th World Health Assembly (WHA) considered the report on the elimination of avoidable blindness (doc A56/26) and urged Member States to support themselves in supporting the Global Initiative for the Elimination of Avoidable Blindness by setting up a national Vision 2020 plan by 2005; (2) Establish a national coordinating committee for Vision 2020, or a national blindness prevention committee to help implement the plan; (3) Implement the plan by 2007; (4) Include effective monitoring and evaluation of the plan with the aim of showing a reduction in the magnitude of avoidable blindness by 2010; (5) To support the mobilisation of resources for eliminating avoidable blindness. The WHA also urged the Director-General to maintain and strengthen WHO’s collaboration with Member States and the partners of the Global Initiative for the Elimination of Avoidable Blindness as well as aid in the coordination and support of national capability.

MSc course in Community Eye Health
The International Centre for Eye Health is offering a full time MSc course in Community Eye Health from 29 September 2003 to 19 September 2004. The course is not clinical and is specifically aimed at health professionals wanting to work in the field of community eye health. The course is designed in keeping with the aims, priorities, and strategies of Vision 2020—the Right to Sight. The course costs £3939 for home students and £14110 for overseas students. Further information: The Registry, 50 Bedford Square, London WC1B 3DP, UK (tel: +44 (0)20 7927 2239; fax: +44 (0)20 7732 0638; email: Adrienne.Burrough@lshtm.ac.uk; website: www.lshtm.ac.uk).

Ophthalmic Anesthesia Society (OAS)—17th Scientific Meeting
The 17th Scientific Meeting of the Ophthalmic Anesthesia Society (OAS) will be held 3–5 October 2003 at the Westin Michigan Avenue Chicago, Chicago, USA. Programme co-chairs: Marc Allen Feldman MD MHS and Steven T Charles MD. The CME joint sponsor is the Cleveland Clinic Foundation; CME hours are pending. Fees for OAS members are $300; non-members $475; students $50. Further details: OAS, 793-A Foothill Blvd, PMB 119, San Luis Obispo, CA 93405 USA (tel: +1 805 534 0300; fax: +1 805 534 9030; email: info@eyeaneesthesia.org; website: www.eyeaneesthesia.org).

Glaucmra Society 24th Annual Meeting and Dinner
The Glaucmra Society 24th Annual Meeting and Dinner will take place on 20 November 2003, from 8.30 am to 9.00 pm at The Royal College of Physicians, London, UK. Further details: Ms Janet Flowers (email: glaucmra@ukiere.freeserve.co.uk).

Detachment Course with international faculty on: Retinal and Vitreous Surgery with Case Presentations preceding the Annual Meeting of Iranian Society of Ophthalmology
The detachment course with international faculty on: Retinal and Vitreous Surgery with Case Presentations preceding Annual Meeting of Iranian Society of Ophthalmology will be held on 29–30 November 2003 and 1–4 December 2003 respectively, at the Razi Conference Center, Hemmat Hyw, Tehran, Iran. Further details: Scientific programme: Prof Ingrid Kreissig, University of Tuebingen, Schleichstr. 12, Breuningerbau, 72076 Tuebingen, Germany (tel: +49 7071 295209; email: ingrid.kreissig@med.uni-tuebingen.de). Local organisation: Dr Arman Masheyekhi, Dr Siamak Moradian, Dept of Ophthalmology, Labbanfinejad Medical Center, Pasdaran Ave, Boosan 9, Tehran, 16666, Iran (fax: +98 21 254 9039; email: labbafi@hotmail.com).

5th International Symposium on Ocular Pharmacology and Therapeutics (ISOPT)
The 5th International Symposium on Ocular Pharmacology and Therapeutics (ISOPT) will take place 11–14 March 2004, in Monte Carlo, Monaco. Please visit our website for details of the scientific programme, registration, and accommodation. To receive a copy of the Call for Abstracts and registration brochure please submit your full mailing details to http://www.kenes.com/isopt/interest.htm. Further details: ISOPT Secretariat (website: www.kenes.com/isopt).

XVth Meeting of the International Neuro-Ophthalmology Society
The XVth Meeting of the International Neuro-Ophthalmology Society will take place 18–22 July 2004, in Geneva, Switzerland. Further details: Prof. A Safran, University Hospital Geneva, c/o SYMOPRG SA, Geneva (fax: +4122 839 8484; email: info@ symoprg.ch; website: www.symoprg.ch).
