The use of magnetic resonance imaging in the diagnosis of suspected giant cell arteritis

Giant cell arteritis (GCA) is a vasculitis of unknown origin that has a predisposition for the cranial arteries in the elderly. It has potentially devastating visual complications and produces a broad range of symptoms and signs that mimic many other medical and surgical conditions. Blood tests reflect the underlying inflammatory process, yet the surgical conditions. Blood tests reflect the presence of giant cell (temporal) arteritis (traditional format)

Methods and results

A prospective, pilot, single masked study of seven female patients (age range 60–88 years, mean 76 years) with suspected giant cell arteritis, and two age matched healthy controls was undertaken. Local research ethical approval and informed written consent were obtained. All patients underwent a standard clinical examination including a detailed history and clinical examination. Investigations included ESR and C reactive protein (CRP). Each patient was given a GCA criteria “score” based on the 1990 ACR (American College of Rheumatology) classification (Table 1). Within 48 hours of presentation patients underwent a unilateral temporal artery MRI scan on a 1.5T scanner using a surface coil and small field of view. T1 and T2 weighted images perpendicular to an affected artery. We conclude that there is an increased potential of MR angiography and gadolinium contrast MRI in demonstrating the vessel changes of GCA.

We compared the ability of MRI to detect changes in the temporal arteries with TAB in patients clinically suspected of having GCA.

Comment

Although our study sample was small our findings suggest that MRI scanning was unable to distinguish between a normal and an affected artery. We conclude that there is no potential for the use of MRI scanning without contrast enhancement in the evaluation of patients with suspected GCA.

Bilateral ischaemic optic neuropathy and stroke after multiple bee stings

Despite the common occurrence of insect stings and local and systemic allergic reactions, there are few reports of optic neuropathy or stroke following bee or wasp stings and, to our knowledge, there has been no report of both cerebral infarction and optic neuropathy occurring in the same patient after such an event. We report on a middle-aged woman who sustained both a stroke and ischaemic optic neuropathy after multiple bee stings.

Case report

A 57 year old white woman reported being stung by 30–40 bees, identified as Africanised honey (killer) bees, in the back of her neck, head, right eye, face, and right arm. She was treated with intravenous antihistamines and antiepileptics at a local emergency room and released.

Two days later, the patient experienced a severe headache with nausea and vomiting and noticed a left homonymous visual field loss. She went to see her primary doctor and while there became unresponsive, leading to hospitalisation. Head computed tomography (CT) showed a right occipital ischaemic infarct.

Shortly thereafter, the patient experienced acute nausea and vomiting with neck rigidity and was admitted. A head CT scan and brain magnetic resonance image (MRI)/magnetic resonance angiography (MRA) were performed showing a large right temporoparietal ischaemic haemorrhagic infarct (fig 1A, B). An ophthalmic examination revealed best corrected visual acuity (BCVA) of 20/20 right eye and 20/30 left eye at distance and 20/20 right eye and 20/200 left eye at near, with left homonymous hemianopia, a left inferior homonymous hemianopic defect with a right altitudinal defect.

Figure 1 MRI (A), MRA (B), and Humphrey 30-2 visual fields (C) of our patient.

Comment

In their literature review of five cases and report of two additional cases of optic neuropathy occurring after bee and wasp sting, Maltzman, et al describe common characteristics, such as acute to subacute onset of symptoms, moderate to severe visual loss followed by significant recovery (except in one case of a sting directly to the eye); oedematous and haemorrhagic optic discs, and central or caecocentral scotomas. Although our patient had subacute vision loss associated with haemorrhagic disc oedema, her case differs because of minimal recovery of vision and altitudinal visual loss consistent with an ischaemic neuropathy, rather than a transient optic neuritis.

Seven cases of wasp and bee sting associated cerebral infarction were found in the literature. Reported neurological complications included seizure, hemiparesis, aphasia, apraxia, dysarthria, ataxia, and coma, none of which were experienced by our patient. None of these patients had a full eye examination, although in one patient a right homonymous superior quadrantanopia was demonstrated.

The pathophysiology explaining the associated stroke is unknown. Hypotension caused by anaphylaxis may certainly induce cerebral and optic nerve ischaemia; however, this was not documented in our case. Similar to acute myocardial infarction after hymenoptera stings, it has been suggested that vasoconstriction secondary to mediators released after the sting, aggravated by exogenous adrenaline, and platelet aggregation also contribute to cerebral ischaemia. Bee venom itself contains histamine, thromboxane, leucotrienes, and other vasoactive and inflammatory mediators. In our patient, we postulate that the systemic immune mediated reaction to the bee sting caused vasoconstriction and a prothrombotic state with subsequent ischaemia leading to both the stroke and AION. In addition, a neuropharmacological (sympathetic) mechanism of endothelial permeability involving the cerebral vasculature with a concurrent systemic thrombogenic or immune response has also been postulated.

adduction in both eyes.

Figure 1 Preoperative V pattern exotropia, over-elevation in adduction, under-depression in adduction in both eyes.

Case report
This child with craniosynostosis had undergone six previous cranial surgeries. She had three strabismus surgical procedures including anterior transpositions of the inferior obliques in an attempt to correct a large V pattern. She presented to us with a chin up position, V pattern exotropia (60 prism dioptres), over-elevation in adduction, limitation of depression in adduction, and incomitant hypertropias in side gazes (fig 1). Objective fundus excyclotorsion was noted.

Orbital imaging demonstrated that all extraocular muscles in each eye were present, normal in size and shape but anatomically displaced. The extraocular muscles in the left eye were rotated clockwise and in the right eye were rotated counterclockwise (fig 2). Ineffectiveness of inferior oblique weakening procedures and the presence of muscle heterotopy led us to consider that the over-elevation in adduction was most likely related to the anatomical displacement of the rectus muscles.

Surgical exploration confirmed muscle heterotopy. The lateral recti were found slanting inferiorly (fig 3). Repositioning of the lateral recti superiorly to a more horizontal position and suturing the superior border of the muscle belly to the adjacent sclera about 18 mm from the limbus using a...
non-absorbable suture was the first surgical procedure performed by us on this patient. This led to some improvement of the V pattern. This was followed by recession and nasal repositioning of the superior rectus suturing the nasal border of the muscle belly to the adjacent sclera about 18 mm from the limbus using a non-absorbable suture. This achieved good alignment in the primary position and eliminated the anomalous chin up position, markedly reduced the V pattern, eliminated the over-elevation in adduction, and improved depression in adduction (fig 4).

Comment
V pattern strabismus in craniosynostosis may be related to anatomical malposition of the rectus muscles. This may be documented by orbital imaging, which could also aid in planning the surgical approach. In these cases the overelevation in adduction and under depression in adduction may be due to the anatomical displacement of the rectus muscles.7

West Nile virus chorioretinitis

West Nile virus has been described in Africa, Europe, the Middle East, west and central Asia, Oceania, and has emerged in recent years in temperate regions of Europe and North America.7 West Nile virus was first isolated from a febrile adult woman in the West Nile District of Uganda in 1937 and became recognised as a cause of severe human meningoencephalitis in elderly patients during an outbreak in Israel in 1957.8 In 1999, the plight of city birds and a collection of human encephalitis cases in New York heralded the arrival of West Nile virus on this side of the Atlantic. From 1999 through 2001, there were 149 cases of human West Nile virus infection in the United States, including 18 deaths, but in 2002 alone more than 3500 cases and 200 deaths were reported.9 In 2003, over 9000 cases were reported with more than 300 cases of neuroinvasive disease.

The Centers for Disease Control notes that neuroinvasive disease includes those cases resulting in meningitis, encephalitis, or meningoencephalitis.7 Cases with ocular involvement should probably be included in this category as well. As our clinical experience in such cases evolves so does our understanding of the ophthalmic manifestations of the disease. Here, we present a case of ocular involvement with West Nile virus, highlighting the typical ocular findings.

Case report

An 80 year old man convalescing in a nursing home from neurological complications of recently acquired West Nile virus meningoencephalitis presented with bilateral visual loss of unspecified duration. The patient had been hospitalised 4 months previously for serologically confirmed West Nile virus encephalitis. His infectious course was complicated by residual right sided paresis, dysarthria, and generalised mental status changes with dementia. Over the following months as he regained his mental faculties he complained to family members of decreased vision and central scotomas, worse in his left eye than right. His best corrected visual acuity at this time was 20/40 in the right eye and 20/60 in the left eye. The patient’s ophthalmic and medical histories were otherwise non-contributory. Biomicroscopic examination revealed normal anterior segments without inflammation and moderate nuclear sclerotic and cortical changes involving both crystalline lenses. Funduscopy examination revealed mild vitreous debris with moderately large areas of retinal pigment epithelial and chorioidal atrophy in the posterior segment (fig 1A and B, right and left eyes, respectively) in addition to partially atrophic and pigmented chorioretinal foci throughout the retinal periphery (fig 2A and B, right and left eyes, respectively).

Over the next 3 months the patient developed problems with his activities of daily living at night and glare with lighting. Subsequent examination revealed progression of the lenticular changes and the patient was referred for cataract extraction. He returned 3 months later after uneventfully cataract surgery. He was not on any medications at this time. Best corrected visual acuity measured 20/30 in the right eye and 20/40 in the left eye. Normal anterior segments without inflammation and well placed posterior chamber intraocular lenses were noted. The vitreous debris persisted and his funduscopic examination was without change bilaterally. Examination 6 months later and approximately 16 months after initial West Nile virus infection demonstrated stable ophthalmic findings and visual acuity.

Comment

Although ocular symptoms associated with West Nile virus were first reported in 1996 ocular findings in West Nile virus infection were first described in the medical literature soon after the West Nile virus epidemic in North America in 2002.8,9 Initial reports described analogous clinical findings consisting of mild anterior segment inflammation, vitritis, and discrete nummular outer retinal/choroidal lesions which were often linear in distribution and varied in appearance from “creamy whitish-yellow” to atrophic with various degrees of pigmentation.8–9 Mild retinal haemorrhage was also occasionally present. Fluorescein angiography revealed these “target” lesions to be hypofluorescent centrally and hyperfluorescent peripherally. Leakage from the optic nerve is sometimes present as optic neuritis and papilloedema may be associated with contiguous central nervous system involvement.8,9 Later reports confirmed these findings and suggested that active lesions associated with vitritis may appear “creamy” in nature eventually progressing to foci of well circumscribed chorioretinal atrophy as the disease becomes inactive and subsequently becoming more prominent with time.8,9 Occulsive vasculitis without chorioretinal findings has also been noted in an isolated case.8 Various ocular inflammatory and infectious processes such as toxoplasmosis and juvenile rheumatoid arthritis have been associated with periods of recurrence and

Figure 1 Moderately large areas of retinal pigment epithelial and chorioidal atrophy with mild pigmentary disturbance of both foveae are present bilaterally, to a greater degree in the left eye (B) compared to the right (A).

Figure 2 Partially atrophic and pigmented chorioretinal foci analogous to those noted in previous reports are distributed throughout the retinal periphery in the right (A) and left (B) eyes respectively.
This highlights an important issue with regard to West Nile virus infection as the risk for neuroinvasive disease is higher for people 50 years of age and older, many of whom are currently or soon will be candidates for cataract extraction. Our patient did well with routine postoperative care and surveillance after uncomplicated cataract extraction in an eye previously affected by West Nile virus chorioretinitis. The eye remained quiescent without evidence of uveitis or reactivation of previously affected fundus lesions. Although surveillance would be recommended for these patients, our findings suggest that chorioretinitis associated with West Nile virus appears to be an acute self limited process without residual sequelae after subsequent intraocular surgery.

We present a complication arising from the use of swimming goggles in a patient with West Nile virus chorioretinitis associated with West Nile virus encephalitis. West Nile virus meningitis with optic neuritis.

Reactivations of ocular toxoplasmosis after cataract extraction. Ophthalmology 2003;130:1732–4.

Previous reports of barotrauma sustained while wearing overtight goggles include suction petechiae and changes in the eyelid skin, but we are not aware of any information concerning the effects of swimming goggles on glaucoma drainage blebs. When goggles are applied, firm pressure displaces a small volume of air and creates a negative “intragoggle” pressure, the basis by which a seal is maintained. In a person who has undergone trabeculectomy, an increase in the transconjunctival pressure gradient could open up a weakness in the perimeter of the bleb and cause it to extend in the direction of least resistance. Other experimental work has examined the pressure changes occurring in the mask space during scuba diving. This is a rather different system as the nose is included in the mask, allowing the pressure to be equalised by exhaling through the nose. The eye and periorbital structures can be subjected to significant negative pressures if this is not done, but the duration is usually limited by this pressure gradient acting across the tympanic membrane, causing pain and prompting the diver to ascend or equalise. Ocular barotrauma can result in subconjunctival haemorrhage and chemosis, and it has been recommended that patients wait a minimum of 2 months after glaucoma filtering surgery before resuming scuba diving.

We do not believe patients who have undergone trabeculectomy need to cease swimming, but they should be aware that goggles may be able to produce excessive negative pressure if they form a very tight seal.

Case report
A 73 year old white man with poorly controlled primary open angle glaucoma underwent routine trabeculectomy with adjunctive 5-fluorouracil to the right eye, followed by the same procedure to the left eye 6 weeks later. Preoperatively the intraocular pressures were 28 mm Hg bilaterally and cup-disc ratios were 0.95 right, 0.8 left. Early postoperative intraocular pressure (IOP) in the right eye was low (5 mm Hg at weeks 2 and 6), but uncomplicated. The recovery of the left eye was uneventful, and at 3 months the IOPs were 10 mm Hg right eye, 12 mm Hg left.

However, at 4 months the patient presented with discomfort and redness in the right eye. A large extension of the bleb had formed at the nasal limbus, with an associated corneal dell (fig 1A and B). The IOP had increased in the right eye, which was treated with a needling procedure and 5-FU injection, repeated 3 weeks later. Subsequently the bleb extension receded and the previously elevated right nasal conjunctiva was found to be firmly adherent to the underlying sclera (fig 1C).

He re-presented 7 months after the initial surgery with redness and swelling, this time in the left nasal conjunctiva (fig 1D). At this point the patient mentioned that he was a keen swimmer and inquired whether his problem could have been caused by the use of swimming goggles. He had resumed regular swimming 2 weeks before developing the right eye complication, then stopped. He had resumed again 3 months before developing the left.

With this in mind, we set out to investigate the pressure changes inside swimming gog- gles. With a pressure transducer fixed to one eye-piece (fig1E), we recorded a comfortable range of ~1 to ~5 mm Hg, discomfort over ~10 mm Hg and a maximum suction of ~44 mm Hg. Upon removing the goggles, a transient negative pressure spike was also produced (fig 1F). Given these observations and the timing of the clinical events, we surmise that the patient’s bleb extensions were plausibly consequent upon his aquatic activities.

Comment
Previous reports of barotrauma sustained while wearing overtight goggles include suction petechiae and changes in the eyelid skin, but we are not aware of any information concerning the effects of swimming goggles on glaucoma drainage blebs. When goggles are applied, firm pressure displaces a small volume of air and creates a negative “intragoggle” pressure, the basis by which a seal is maintained. In a person who has undergone trabeculectomy, an increase in the transconjunctival pressure gradient could open up a weakness in the perimeter of the bleb and cause it to extend in the direction of least resistance.

Immune recovery disease: a case of interstitial keratitis and tonic pupil following bone marrow transplantation

Immune recovery disease results from an immunological response to circulating viral antigens in the host after bone marrow transplant (BMT) mediated immune reconstitution. It may also occur after successful antiretroviral therapy in patients with HIV and AIDS. We report a case of a child with severe combined immune deficiency (SCID) and acquired varicella zoster virus (VZV) infection who developed interstitial keratitis and a tonic pupil after BMT.

Case report

An 8 month old male infant was referred to the ophthalmology clinic at Great Ormond Street because of suspected congenital glaucoma. The past ophthalmic and family history were unremarkable. The child was born with multiple congenital anomalies of the lower limbs which included bilateral tibial deficiencies, and an extreme talipes equinovarus of the right foot. The child had a known history of disseminated varicella infection caused by SCID (fig 1). On examination it was noted that he had a generalised vesicular rash throughout his body extending to his eyelid margins. The eyes were white with clear corneas and he was alert, fixing and following well with full extraocular eye movements. Both pupils were reactive to light with no afferent pupillary defect. The anterior chambers were unremarkable and the intraocular pressure with the Perkins tonometer was 16 mm Hg bilaterally. Examination of the fundus, including cup to disc ratio was normal. He was reviewed periodically over the next 6 months while an inpatient undergoing treatment for SCID. During this period, he was persistently positive for VZV DNA in his blood determined by polymerase chain reaction (PCR) analysis but was negative for Epstein-Barr virus (EBV), herpes simplex virus (HSV), cytomegalovirus (CMV), and adenovirus DNA. He suffered a number of exacerbations of the varicella infection and was treated with systemic aciclovir, foscarnet, and cidofovir.

At 12 months of age he underwent allogeneic BMT from a one antigen mismatched unrelated donor following reduced intensity conditioning with fludarabine, melphalan and alemtuzumab. Engraftment was very rapid with neutrophils appearing by day 10. Before BMT the CD3+ CD4+ count was 0.04 × 10^9/l but 7 weeks after BMT the CD3+ CD4+ count was 0.47 × 10^9/l.

Four weeks after BMT his mother noted bilateral corneal haze which was more marked on the left eye. He was reviewed in his isolation cubicle with a hand held slit lamp and Perkins tonometer and was found to have bilateral corneal stromal haze and corneal vascularisation (fig 2). There was no conjunctival injection, and his intraocular pressure was 13 mm Hg in each eye. Both pupils were reactive to light. The lymphocyte count had recovered at this point to more than 1.0 × 10^9/l.

An examination under anaesthesia was arranged and a diagnosis of interstitial keratitis without epithelial involvement was made. He was treated with intensive topical prednisolone acetate 1% (one drop every 2 hours) and cyclopentolate 1% twice daily to both eyes. Betaxolol 0.5% twice daily was prescribed prophylactically to prevent raised intraocular pressure which could exacerbate the corneal haze. The child was reviewed regularly and the stromal vascularisation was seen to regress. He was thus gradually weaned off the steroid drops to one drop daily and the cycloplegics were stopped. Three months after BMT his mother reported a change in pupillary size in the right eye. On examination the right pupil was mid-dilated and oval in shape, not reactive to light and there was no evidence of posterior synechiae (fig 3). A diagnosis of a right tonic pupil was made.

At the most recent review, 6 months following BMT he had clear corneas centrally in both eyes with some persistent peripheral stromal vessels, and a right tonic pupil. Unaided visual acuity was 0.60 logMAR with stromal vessels, and a right tonic pupil. The child was reviewed periodically over the next 6 months while an inpatient undergoing treatment for SCID. During this period, he was persistently positive for VZV DNA in his blood determined by polymerase chain reaction (PCR) analysis but was negative for Epstein-Barr virus (EBV), herpes simplex virus (HSV), cytomegalovirus (CMV), and adenovirus DNA. He suffered a number of exacerbations of the varicella infection and was treated with systemic aciclovir, foscarnet, and cidofovir.

Currently, the child has an ongoing mild chronic graft versus host disease affecting the skin and intestine which is controlled with low dose systemic steroids. His systemic medications also include aciclovir 120 mg four times daily.

Comment

Severe combined immune deficiencies (SCID) are a rare heterogeneous group of disorders characterised by severe T cell and B cell deficiency with low or absent antibody levels. They usually manifest in the first months of life with severe and recurring infections leading to death often by the age of 2 years.

Since 1968 these diseases have been successfully treated with haemopoietic stem cell transplantation. Varicella infection has been associated with severe immune dysfunction following BMT and it has been shown that severe disseminated varicella infection causes ocular disease that mimics the sequelae of herpes zoster ophthalmicus.

In the adult population, the commonest cause of interstitial keratitis is HSV infection whereas varicella infection is considered a rare cause. In children, although varicella infection is extremely common, ocular complications of this disease are rare.

If keratitis develops in association with a childhood viral exanthem it is important to consider a number of possible infectious agents such as HSV, EBV, mumps, syphilis, Lyme disease, or tuberculosis in the differential diagnosis. In this setting, other documented complications in association with SCID include bilateral viral endophthalmitis, CMV retinitis, and optic neuritis. In this case the history and the physical findings were highly suggestive of the diagnosis and were confirmed by PCR testing. As far as we are aware this is the first case of varicella

Figure 1 Photograph of the child with severe systemic varicella a few days after admission.

Figure 2 Photograph of the left eye showing deep and superficial corneal stromal vessels.

Figure 3 Photograph of the right eye showing the tonic pupil and corneal stromal vascularisation.
associated interstitial keratitis and a tonic pupil occurring in a child with SCID following BMT. The signs of early interstitial keratitis and a right tonic pupil were noted by the child’s mother about 4 weeks after the allogeneic bone marrow transplant. We believe that an immunological response to pre-existing varicella was responsible for the development of the eye signs. This signifies a positive response from a nascent immune system in the recipient—an example of immune recovery disease.

There is experimental evidence to support this as it has been shown that whole lymphocyte and splenocyte transfer leads to herpes simplex keratitis in SCID mice. In other words SCID mice reconstituted with T lymphocytes of the CD4+ phenotype developed subsequent corneal lesions in relation to HSV infection. Conversely Mercadal et al. have shown that unreconstituted SCID mice remained lesion free when infected with HSV. This suggests that herpes simplex keratitis is a T cell mediated immunopathological reaction to virus in the cornea. In our case the corneal changes occurred following bone marrow reconstitution. Before BMT the CD3+ CD4+ count was 0.04 x 10^9/l but 7 weeks following BMT the CD3+ CD4+ count was 0.47 x 10^9/l. The corneal changes become apparent at about 4 weeks after BMT. We believe that our case illustrates a similar mechanism in the human model in relation to varicella infection.

The tonic pupil developed as a consequence of a post-viral ganglionitis affecting the ciliary ganglion and the short posterior ciliary nerves, a rare but previously described complication of varicella infection. Other reported cases of ophthalmic immune recovery disease include a case of varicella zoster virus associated anterior stromal keratitis in a patient with AIDS and, in another case, in association with CMV retinitis.

Considering BMT, varicella zoster virus associated disease can be a frequent complication following autologous and allogeneic transplantation. Other complications in relation to BMT include pseudomembranous conjunctivitis, keratoconjunctivitis sicca, cataracts, and severe graft versus host disease.

This child did suffer a graft versus host disease-like rash at the time of the development of the keratitis. While it is possible that the keratitis was purely Graft versus host disease this seems unlikely, given that there was no conjunctival involvement and that the graft versus host disease was extremely mild. Furthermore, in this case the disseminated varicella infection preceded the BMT and formed the basis for identifying a severe immune deficiency in the child. It highlights the importance of frequent opthalmic follow up in the immediate period following BMT as there is an increased risk of oculocutaneous disease.

The age at the onset of symptoms in OMD patients is relatively old,1–3 and the first visit to the hospital is aged 20 years or more with the youngest being 16 years old. Here, we present an 11 year old boy who was diagnosed as having OMD because of the results of electrophysiological and psychophysical tests.

Case report
An 11 year old boy was referred to our hospital with a complaint of progressive decline of vision in both eyes. His corrected visual acuity was 20/25 in both eyes at 6 years of age, but had decreased to 20/33 at 10 years of age. Family history revealed none of the members to have any eye diseases. At the initial examination, his visual acuity was 20/40 right eye and 20/33 left eye with -3.0 dioptres (D) in both eyes. The fundus examination and fluorescein angiograms were normal (fig 1). The peripheral visual fields were intact but a relative central scotoma was detected in the 1-2 target within 10 degrees in both eyes. A moderate red-green defect was found in the Ishihara pseudosochromatic plates, Hardy-Rand-Rittler pseudosochromatic plates, and Farnsworth-Munsell 100 hue test.

The amplitude of full field ERGs were within the normal range for both rod and cone components (fig 2A). However, focal macular ERGs with 5, 10, and 15 degrees stimulus spots were severely reduced and essentially absent (fig 2B). The multifocal ERGs demonstrated a loss of local responses in the central retina (fig 2C).

Psychophysical rod and cone sensitivity was performed on his right eye with 31 test points across the 60 degree horizontal meridian using a previously described method. The cone sensitivities were severely affected in the central retina but fell within the normal range in the periphery (fig 2D). The rod sensitivities were at the lower borderline at almost all locations tested (not shown).

At present (August 2003, 13 years old), his acuity has decreased to 20/50 in both eyes, but his fundi still remain normal in both eyes.

Comment
This boy had a progressive decrease of visual acuity in both eyes, and his fundus examinations and fluorescein angiograms were completely normal. The amplitude of the conventional full field ERGs were also within the normal range for both rod and cone components. However, focal macular cone ERGs and multifocal ERGs were severely reduced in the central retina. Results of psychophysical perimetry showed a reduction of cone sensitivity but only in the central retina. These findings are consistent with the clinical characteristics of OMD which we have previously reported.1–4

OMD in children is very rare.5–11 In our 42 consecutive OMD patients seen at the Nagoya University Hospital from 1988 to 2003, the age at initial visit to the hospital ranged from 16 to 74 years (mean 45.8 years), and 95.2% of patients visited the hospital at 20 year old or more. Based on the best of our knowledge, this boy is the youngest case with OMD reported anywhere.

We would like to emphasise that OMD can be found even in children. Because the fundus examination and full field ERGs are normal in these patients, these children are apt to be misdiagnosed as optic nerve disease, central nerve disease, or psychological
disorders. Focal or multifocal ERG techniques are the only key to diagnose this rare type of macular dystrophy.

Pseudomonas aeruginosa microbial keratitis secondary to cosmetic coloured contact lens wear

Cosmetic coloured contact lenses are worn to give the appearance of a different or unusual eye colour and about 60 000 people in the United Kingdom obtain these types of contact lenses through eye care professionals. A subset of these lenses—those with no optical power (“plano” coloured lenses)—falls outside legislation designed to restrict the sale of contact lenses to suitably qualified professionals. We report a severe case of microbial keratitis caused by Pseudomonas aeruginosa which has resulted in lasting visual impairment in a patient obtaining cosmetic coloured contact lenses from a fashion shop rather than through an eye care practitioner.

Case report
An 18 year old south Asian male student presented in December 2003 with a 2 day history of a foreign body sensation in his left eye. One day before presentation the eye had become slightly red. He had commenced the use of Brolene eye drops which had been purchased from a large chain supermarket. The eye then became painful with eyelid swelling and he presented to the local district general hospital the following day. He was diagnosed with a corneal ulcer and referred to our institution.

He reported a 12 month history of cosmetic coloured plano contact lens wear, having purchased the lenses from a fashion shop rather than through an eye care professional.
No counselling was provided at the point of purchase regarding a hygiene routine, care of lenses, or possible complications associated with their use. He wore the lenses 12 hours per day, 7 days per week without any overnight use. The lenses were designed to make the eye appear grey or blue (patient’s natural eye colour was brown). There was no past medical or ocular history of note including amblyopia.

On examination the unaided vision was 6/6 in the right eye and 6/36 in the left eye. The left eye demonstrated a mid-peripheral corneal infiltrate in the 4 o’clock position with overlying 2.4 mm diameter ulcer, and surrounding stromal swelling (Fig 1). There was a 0.5 mm height hypopyon. The intraocular pressure was within the normal range. The right cornea demonstrated a very small peripheral infiltrate with no significant anterior chamber reaction. Both posterior segments were unremarkable. A corneal scrape was performed with the Gram stain demonstrating a small quantity of neutrophils and Gram negative bacilli. Ofloxacin 0.3% drops were commenced every hour to the left eye. The peripheral infiltrate resolved with the corneal epithelial healed by day 10. Topical prednisolone 0.5% was commenced on day 4. A more central mid stromal corneal infiltrate encroaching on the visual axis developed on day 1 after admission and has gradually become less prominent during follow up over 3 months (Fig 2) although the visual acuity remains reduced at 6/36. *Pseudomonas aeruginosa* was grown from the corneal scrape, sensitive to ciprofloxacin, ofloxacin, gentamicin, and ceftazidime. The right eye was not scraped, responded well to topical ciprofloxacin, and did not develop any scarring.

In the United Kingdom, the Opticians Act 1989 states that a person who is not a registered medical practitioner or registered optician shall not fit contact lenses. Plano (or “afocal”) contact lenses are not included in this act because they have no optical power. The General Optical Council has received reports of these lenses being shared and exchanged between wearers and of sales staff demonstrating fitting on themselves before offering the lens to the purchaser. In November 2000 the General Optical Council submitted recommendations to the Department of Health arguing that primary legislation should be passed stipulating that the fitting and sale of plano contact lenses should also fall within the terms of the act. On 28 October 2003 Mr John Robertson, MP for Anniesland, Glasgow, moved a bill to amend the Opticians Act 1989 to include plano contact lenses in the restrictions already placed on the sale of other contact lenses.4 

This case report highlights the potential complications of these lenses and supports legislation restricting their sale.

**Severe proliferative retinopathy in a patient with advanced muscular dystrophy**

The patient is a 25 year old white man with Duchenne muscular dystrophy (DMD), complicated by respiratory failure requiring ventilatory assistance and impaired cardiac function. His ocular complaints were “floaters” and decreased vision over the preceding 6 weeks. He had no history of ocular disease or trauma. The patient’s level of alertness was reported to routinely fluctuate but no new neurological findings were present. The best corrected visual acuity was count fingers in the right eye and 20/70 in the left eye. The intraocular pressures were 14 and 8 mm Hg. The anterior segment examination was unremarkable with no neovascularisation of the iris or angle. Biomicroscopy revealed bilateral vitreous haemorrhage. Indirect ophthalmoscopy showed the retinal periphery to be attached in both eyes. The optic discs and macula were partially obscured by haemorrhage. Fluorescein angiography revealed delayed filling and venous beading in both eyes, without central or branch, vascular occlusion. Hyperfluorescence, consistent with neovascularisation, was present along the temporal vascular arcades and at the optic discs. Fundus photography corroborated the angiographic findings (see figs 1 and 2) and indirect laser with scleral depression resulted in full treatment of retina outside of the vascular arcades. Treatment appeared to have little effect on neovascular progression. Overwhelming anaesthetic risk prevented intraocular procedures. Both eyes progressed to subtotal traction retinal detachment and counting fingers vision.

**Comment**

The working diagnosis was retinal ischaemia secondary to hypoperfusion or pan-microvascular occlusive disease. The cardiac ejection fraction was 20% of predicted; the forced vital capacity was 14% of predicted and the forced expiratory volume in 1 second was 15% of predicted. We believe that cardiopulmonary compromise was a primary

mice. The Dp71 isoform of dystrophin suffers sufficient to induce neovascularisation alone.

Pathophysiological mechanisms in adults. Retinal neovascularisation is an important factor in the regulation of ischaemic processes in the retina. The morphological changes associated with neovascularisation, such as venous beading, leakage of fluorescein dye, and haemorrhages, are indicative of increased vascular permeability. This increased permeability is thought to be caused by changes in the retinal microvasculature and the surrounding tissues.

The role of dystrophin in retinal neovascularisation

Dystrophin is normally expressed in the retina and localises to photoreceptor terminals and around retinal vessels. Deficiency of dystrophin produces abnormal transmission between photoreceptors and optic nerve bipolar cells and a diminished electroretinogram (ERG) signal. Mice lacking the Dp71 isoform of dystrophin suffer greater damage to the ganglion cell layer following transient ischaemia than wild type mice. Therefore, dystrophin may be involved in the regulation of ischaemic processes in the retina. Cardiopulmonary assist is not routinely associated with proliferative retinopathy. In adults, retinal neovascularisation is not prevalent in the Duchenne population, suggesting that absence of dystrophin is not sufficient to induce neovascularisation alone.

In summary, rapidly progressive, bilateral proliferative retinopathy may be associated with DMD in the presence of severe cardio-pulmonary compromise. Whether an absence of dystrophin contributes directly or indirectly is unknown but consideration of the possibility may lead to novel insights into the development of pathological retinal neovascularisation. The visual prognosis with late presentation in this setting is uncertain despite full panretinal photocoagulation. Patients with advanced DMD may benefit from periodic fundus examination as it is not known whether early treatment has the potential to alter prognosis.

Bilateral decompression retinopathy after orbital decompression surgery

Decompression retinopathy is defined as retinal haemorrhages that typically occur after glaucoma filtration surgery.

Orbital decompression is a common surgery performed to treat patients with thyroid related optic neuropathy for functional or cosmetic indications. Many complications have been described with the surgery, but this surgery has never been associated with retinal haemorrhages.

We describe a case of a 70 year old woman, who developed bilateral retinal haemorrhages after staged bilateral orbital decompression surgeries.

Case report

A 70 year old woman with the diagnosis of euthyroid Graves’ disease was referred because of severe proptosis. Past ophthalmic history revealed two previous strabismus surgeries. Past medical history was unremarkable with no history of diabetes or cardiovascular disease, also she was not taking aspirin or any other blood thinning medications.

Ophthalmic examination showed visual acuity of 20/20 in each eye. Both orbits were moderately firm to retroplulsion. IOP was within normal limits in primary gaze (14, 19 mm Hg) and slightly elevated in upgaze (17, 26 mm Hg). There were limitations in upgaze and lateral gaze in both eyes as well as upper and lower lids retractions. There was a mild degree of lagophthalmos with exposure keratopathy. Funduscopy was normal and did not show any evidence of microvascular disease or retinal haemorrhages. Hertel measurements were 22 mm on the right and 23 mm on the left. Computed tomography scan showed enlargement of the extraocular muscles.

She underwent balanced orbital decompression surgery on the left side, including deep lateral and medial wall decompression with intraconal fat removal. Three days after surgery she noted spots in front of her left eye. Visual acuity in that eye was 20/25. Funduscopic examination disclosed dot and blot haemorrhage with flame shaped haemorrhages in the posterior pole of the left eye (fig 1).

The patient was well informed of the complications in the first eye and the chance of developing retinal haemorrhages in the right eye after orbital decompression. She agreed to undergo surgery and 1 week later she underwent balanced orbital decompression on the right side. Three days later she again noted spots in front of her right eye. Best corrected visual acuity decreased to 20/100, and funduscopic examination revealed posterior pole retinal haemorrhages (fig 2).

Three months postoperatively IOP in primary gaze decreased to 12 mm Hg in both eyes, and 14 and 16 mm Hg in upgaze. Exophthalmos decreased to 18 mm on each side, and the lagophthalmos and exposure keratopathy resolved. Fluorescein angiography showed evidence of blocked fluorescence, suggestive of retinal haemorrhage. There was no evidence of neovascularisation, vasculopathy, or choroidal rupture. Visual acuity gradually improved over the course of 3 months and returned to 20/20 in both eyes.

Figure 2. Fluorescein angiogram of the right eye showing venous beading (arrow), leakage from neovascularisation on the disc (arrowheads) and blocking vitreous haemorrhage; the visible retina is attached.
Retinal nerve fibre layer damage after indocyanine green assisted vitrectomy

Recently, indocyanine green (ICG) has been used to stain and visualise the internal limiting membrane (ILM) during vitrectomy. Some case series showed that visual field defects on the nasal side can occur after the surgery through unknown cause. Here, we report a case in which nasal visual field defects occurred after ICG assisted ILM peeling for epiretinal membrane (ERM). Detailed examination revealed that the superior and inferior retinal nerve fibres is severely damaged in this case.

Case report

A 60 year old woman who received ICG assisted ILM peeling for ERM in her right eye was referred to our hospital. The preoperative best corrected visual acuity (BCVA) was 20/25 in the right eye. According to the referring ophthalmologist, 25 mg of ICG (Diagnogreen; Daiichi Pharmaceuticals) was dissolved in 10 ml of distilled water, which was further diluted by a viscoelastic material (Healon; Pharmacia) to give 0.16% ICG solution. To stain ILM, ICG was injected into an air filled eye and the dye was washed 2 minutes later. An air infusion cannula was placed at the temporal side. There was no complication during the surgery. Seventeen days after the operation, she noticed nasal visual field loss, which got worse 22 days after the surgery. Sixty days after the surgery, she was referred to our hospital. At the initial visit, the BCVA was 20/25 in the right eye. Goldmann perimetry revealed a nasal visual field defect (fig 1A). In the right eye, a relative afferent pupillary defect was found. Ophthalmoscopic examination and fluorescein angiography showed no abnormalities. The optic disc rim appeared to have lost colour without being associated any cup or rim changes typically seen in glaucoma (fig 1B). Residual ICG was evident at the optic disc and along the nerve fibre (fig 1C).

The nerve fibre staining was most evident in the superior and inferior quadrants. ICG angiography revealed ICG staining of the optic disc and superior and inferior nerve fibres, but no other abnormalities. Full field electroretinogram (ERG) and multifocal ERG (VERIS science ver3.8, EDI) revealed no abnormalities. The results of visual evoked potential testing were also non-remarkable.

During our 8 month follow up period, there was no significant change in the visual field defect and the distribution of the residual ICG. Scanning laser polarimetric analysis (GDx VCC, Laser Diagnostic Technologies, Inc, San Diego, CA, USA) performed 8 months after the surgery showed profound nerve fibre loss around the disc, especially evident at superior and inferior quadrants (fig 2).

Comment

In this case, an air infusion cannula was placed at the temporal side and Goldmann perimetry showed nasal visual field defects. Thus, the dehydration injury to the retina during air-fluid exchange, which is observed at the opposite side of the cannula, is unlikely to be the cause of this visual field defects. Optic neuropathy unrelated to the use of ICG may be considered as a differential diagnosis. However, this visual field damage is not typically seen in optic neuropathy and may be rather associated with ICG, based on
Competing interest: none.

PostScript 1607

Figure 2  The results obtained from the GDx-VCC from the right (top) and left (bottom) eyes taken 8 months after the surgery. The left column shows the retardation image. The centre column shows the results from analysis. The navy, blue, yellow, and red points represent significant loss of nerve fibre layer, p<5%, 2%, 1%, and 0.5%, respectively. The right column shows that the general double hump pattern is evident in the left eye but is lost in the right eye.

Recent clinical findings. Retinal damage was not evident by morphological, angiographic, and functional analysis. However, it was evident that the nerve fibres are damaged in this patient. Although the direct causal relation cannot be proved, it is highly likely that the damage to the nerve fibres was caused by the ICG because of the remarkable correspondence of the distribution pattern of ICG and the nerve fibre defects. This is also supported by our experimental findings that ICG showed neurotoxicity at concentrations lower than clinically employed. To our knowledge, this is the first report of ICG induced retinal nerve fibre damage assessed by scanning laser polarimetry.

Worldwide clinical trials for new technique for early detection of eye disease

A unique new non-invasive technique for high resolution optical imaging of the eye is receiving global acclaim. The technique, pioneered by the University of Kent, is funded by the Toronto-based company, Ophthalmic Technology Inc (OTI). The University’s Applied Optics Group is currently working with university hospitals in New York (USA), Osaka (Japan), Asahikawa (Japan), Amsterdam (Netherlands) and Milan (Italy) to carry out preliminary clinical trials. By combining two high-resolution imaging technologies, the new technique provides doctors with 3-D images of the retina, macula and the optic nerve. Such high resolution images provide clinicians with capabilities for early diagnosis and treatment of common ocular diseases such as glaucoma, diabetes and age-related macula degeneration. OTI is planning in the near future to extend the clinical research to other leading university medical centres in Japan, USA and Europe.

Professor Adrian Podoleanu explained: ‘At Kent we created a very cost effective imaging system which simultaneously produces optical coherence tomography (OCT) and scanning laser ophthalmoscope (SLO) images. Its early potential was immediately realised by OTI, who commissioned the assembly of several prototypes to be tested in different clinics worldwide before embarking on commercial exploitation of the invention.

The clinical investigators together with the Kent team have jointly published in international medical publications and presented at clinical and scientific conferences over 50 publications and presentations related to this research.
