The use of magnetic resonance imaging in the diagnosis of suspected giant cell arteritis

Giant cell arteritis (GCA) is a vasculitis of unknown origin that has a predisposition for the cranial arteries in the elderly. It has potentially devastating visually complications and produces a broad range of symptoms and signs that mimic many other medical and surgical conditions. Blood tests reflect the underlying inflammatory process, yet the erythrocyte sedimentation rate (ESR) may be normal in 8% of patients with biopsy-proved GCA. Nevertheless, making a definitive diagnosis has importance therapeutically as patients are committed to a lengthy oral corticosteroid regimen. Non-invasive techniques, such as colour Doppler or duplex ultrasonography, have been studied in an attempt to improve patient preselection for temporal artery biopsy (TAB). Magnetic resonance imaging (MRI) has been shown to improve the diagnosis of early Takayasu arteritis. More recently several case reports have described the diagnostic potential of MR angiography and gadolinium contrast MRI in demonstrating the vessel changes of GCA.

We compared the ability of MRI to detect changes in the temporal arteries with TAB in patients clinically suspected of having GCA.

Methods and results

A prospective, pilot, single masked study of seven female patients (age range 60–88 years, mean 76 years) with suspected giant cell arteritis, and two age matched healthy controls was undertaken. Local research ethical approval and informed written consent were obtained. All patients underwent a standard clinical examination including a detailed history and clinical examination. Investigations included ESR and C reactive protein (CRP). Each patient was given a GCA criteria “score” based on the 1990 ACR (American College of Rheumatology) classification (Table 1). Within 48 hours of presentation patients underwent a unilateral temporal artery MRI scan on a 1.5T scanner using a surface coil and small field of view. T1 and T2 weighted images perpendicular to the temporal artery and a time of flight sequence were obtained. The MRI visualised the location of the temporal artery that was subsequently biopsied in a standard manner within 24 hours of the scan. Two healthy age matched controls also underwent a medical assessment, ESR and CRP, and an MRI as detailed above, but a TAB was not performed. The MRI scans were reported by an independent, masked neuroradiologist.

Each patient’s ACR criteria “score” and the results of the MRI scan and TAB are shown in Table 2. The finding of three out of five ACR criteria is associated with a 94% sensitivity and 91% specificity for the diagnosis of GCA. There were two positive and one equivocal TAB result from the seven patients, but no positive MRI findings were identified. However, when using the ACR criteria as “gold standard,” there were two true negative MRI scan results compared with three false negative scan results. The two remaining MRI scans were described as equivocal, in comparison with the ACR criteria—one patient was positive for GCA and the other patient’s ACR criteria “score” was negative for GCA. From the data the negative predictive values of MRI scanning and TAB for GCA were 40% and 50%, respectively. Of the five patients who showed a prompt response to oral corticosteroid, the MRI scan was unable to distinguish between a normal and an affected artery. We conclude that there is no potential for the use of MRI scanning without contrast enhancement in the evaluation of patients with suspected GCA.

Comment

Although our study sample was small our findings suggest that MRI scanning was unable to distinguish between a normal and an affected artery. We conclude that there is no potential for the use of MRI scanning without contrast enhancement in the evaluation of patients with suspected GCA.

Bilateral ischaemic optic neuropathy and stroke after multiple bee stings

Despite the common occurrence of insect stings and local and systemic allergic reactions, there are few reports of optic neuropathy or stroke following bee or wasp stings and, to our knowledge, there has been no report of both cerebral infarction and optic neuropathy occurring in the same patient after such an event. We report on a middle-aged woman who sustained both a stroke and ischaemic optic neuropathy after multiple bee stings.

Case report
A 57 year old white woman reported being stung by 30–40 bees, identified as Africanised honey (killer) bees, in the back of her neck, head, right eye, face, and right arm. She was treated with intravenous antihistamines and antiemetics at a local emergency room and released.

Two days later, the patient experienced a severe headache with nausea and vomiting and noticed a left homonymous visual field loss. She went to see her primary doctor and while there became unresponsive, leading to hospitalisation. Head computed tomography (CT) showed a right occipital ischaemic infarct.

Shortly thereafter, the patient experienced acute nausea and vomiting with neck rigidity and was admitted. A head CT scan and brain magnetic resonance image (MRI)/magnetic resonance angiography (MRA) were performed showing a large right temporopontine haemorrhagic infarct (fig 1A, B). An ocular examination revealed best corrected visual acuity (BCVA) of 20/20-1 right eye and 20/30-2 left eye at distance and 20/20 right eye and 20/200 left eye at near, with left homonymous hemianopia, a left inferior altitudinal defect, and bilateral arcuate defects (fig 1C) with bilateral haemorrhagic disc oedema.

Past medical and surgical history are significant only for controlled arterial hypertension and pseudohypopituitarism.

Neuro-ophthalmic examination 5 weeks after her sting episode showed BCVA of 20/15 right eye and 20/25 left eye at distance and 20/20 right eye and 20/30-1 at near. Amsler grid and automated perimetry showed a left homonymous hemianopic defect with a right inferior arcuate defect and a left inferior altitudinal defect.

Pupill examination showed isocoria with a 0.3–0.6 log unit relative afferent pupillary defect in the left eye. Motility was unremarkable, as was anterior segment both eyes. Intraocular pressures were 20 mm Hg right eye and 18 mm Hg left eye. Funduscopic examination showed bilateral disc oedema with pallid swelling superiorly and temporally in both eyes and peripapillary haemorrhage and cotton wool spots in both eyes consistent with anterior ischaemic optic neuropathy (AION). Both maculas were remarkable without exudative changes. Both retinas were flat with normal vasculature out to the periphery.

Three months after the sting event, the patient reported some improvement of peripheral vision, and repeat visual fields improved slightly inferiorly but were otherwise unchanged. Both optic discs were now flat and showed superior temporal pallor with corresponding nerve fibre layer dropout.

Comment
In their literature review of five cases and report of two additional cases of optic neuropathy occurring after bee and wasp sting, Maltzman, et al12 describe common characteristics, such as acute to subacute onset of symptoms, moderate to severe visual loss followed by significant recovery (except in one case of a sting directly to the eye); oedematous and haemorrhagic optic discs, and central or caecocentral scotomas. Although our patient had subacute vision loss associated with haemorrhagic disc oedema, her case differs because of minimal recovery of vision and altitudinal visual loss consistent with an ischaemic neuropathy, rather than a transient optic neuritis.

Seven cases of wasp and bee sting associated cerebral infarction were found in the literature.13 Reported neurological complications included seizure, hemiparesis, aphasia, apraxia, dysarthria, ataxia, and coma, none of which were experienced by our patient. None of these patients had a full eye examination, although in one patient a right homonymous superior quadrant anopia was demonstrated (table 1).

The pathophysiology explaining the associated stroke is unknown. Hypotension caused by anaphylaxis may certainly induce cerebral and optic nerve ischaemia; however, this was not documented in our case. Similar to acute myocardial infarction after hymenoptera stings, it has been suggested that vasoconstriction secondary to mediators released after the sting, aggravated by exogenous adrenaline, and platelet aggregation also contribute to cerebral ischaemia.14 Bee venom itself contains histamine, thromboxane, leucotrienes, and other vasoactive and inflammatory mediators. In our patient, we postulate that the systemic immune mediated reaction to the bee sting caused vasoconstriction and a prothrombotic state with subsequent ischaemia leading to both the stroke and AION. In addition, a neuropharmacological (sympathetic) mechanism of endothelial permeability involving the cerebral vasculature with a concurrent systemic thrombogenic or immune response has also been postulated.15

Adduction in both eyes.

Figure 1 Preoperative V pattern exotropia, over-elevation in adduction, under-depression in adduction in both eyes.

Figure 2 Preoperative coronal views on CT scan of both orbits showing evidence of rectus muscle heterotopy. A vertical line joining the centre of the belly of the vertical rectus muscles shows the relative temporal displacement of the superior rectus muscle compared to the nasal displacement of the inferior rectus muscle. A horizontal line joining the centre of the belly of the horizontal rectus muscles shows the relative inferior displacement of the lateral rectus muscle compared to superior displacement of the medial rectus muscle.

Figure 3 Intraoperative photograph. The left eye is adducted with a muscle hook placed under the lateral rectus muscle (LR). The lower line highlights the downward slanting of the left lateral rectus muscle. A curved ruler is used to show the normal horizontal path of the lateral rectus muscle.

Figure 4 Postoperative clinical pictures showing improvement in V pattern exotropia with improvement in versions in adduction.

Cause of V pattern strabismus in craniosynostosis: a case report

Strabismus is a common association in patients with craniosynostosis or craniofacial dysostosis (60–70%). V pattern exotropia is the most common ocular motility problem.

Various theories have been proposed to explain the cause of the V pattern and surgical attempts to correct it with weakening procedures of the inferior oblique have been disappointing.

This is a case report of one child with this disorder who underwent orbital computed tomography (CT) scans and had a marked improvement of the V pattern following strabismus surgery based on the CT findings.

Case report

This child with craniosynostosis had undergone six previous cranial surgeries. She had three strabismus surgical procedures including anterior transpositions of the inferior obliques in an attempt to correct a large V pattern. She presented to us with a chin up position; V pattern exotropia (60 prism dioptries), over-elevation in adduction, limitation of depression in adduction, and incomitant hypertropias in side gazes (fig 1). Objective fundus excyclotorsion was noted. Orbital imaging demonstrated that all extraocular muscles in each eye were present, normal in size and shape but anatomically displaced. The extraocular muscles in the left eye were rotated clockwise and in the right eye were rotated counterclockwise (fig 2). Ineffectiveness of inferior oblique weakening procedures and the presence of muscle heterotopy led us to consider that the over-elevation in adduction was most likely related to the anatomical displacement of the rectus muscles.

Surgical exploration confirmed muscle heterotopy. The lateral recti were found slanting inferiorly (fig 3). Repositioning of the lateral recti superiorly to a more horizontal position and suturing the superior border of the muscle belly to the adjacent sclera about 18 mm from the limbus using a...
non-absorbable suture was the first surgical procedure performed by us on this patient. This led to some improvement of the V pattern. However, this was followed by recession and nasal repositioning of the superior rectus suturing the nasal border of the muscle belly to the adjacent sclera about 18 mm from the limbus using a non-absorbable suture. This achieved good alignment in the primary position and eliminated the anomalous chin up position, markedly reduced the V pattern, eliminated the over-elevation in adduction, and improved depression in adduction (fig 4).

Comment

V pattern strabismus in craniosynostosis may be related to anatomical malposition of the rectus muscles. This may be documented by orbital imaging, which could also aid in planning the surgical approach. In these cases the overelevation in adduction and under depression in adduction may be due to the anatomical displacement of the rectus muscles.7

West Nile virus chorioretinitis

West Nile virus has been described in Africa, Europe, the Middle East, west and central Asia, Oceania, and has emerged in recent years in temperate regions of Europe and North America.7 West Nile virus was first isolated from a febrile adult woman in the West Nile District of Uganda in 1937 and became recognised as a cause of severe human meningoencephalitis in elderly patients during an outbreak in Israel in 1957.7 In 1999, the plight of city birds and a collection of human encephalitis cases in New York heralded the arrival of West Nile virus on this side of the Atlantic. From 1999 through 2001, there were 149 cases of human West Nile virus infection in the United States, including 18 deaths, but in 2002 alone more than 3500 cases and 200 deaths were reported.7 In 2003, over 9000 cases were reported with more than 300 cases of neuroinvasive disease.

The Centers for Disease Control notes that neuroinvasive disease includes those cases resulting in meningitis, encephalitis, or meningoencephalitis.7 Cases with ocular involvement should probably be included in this category as well. As our clinical experience in such cases evolves so does our understanding of the ophthalmic manifestations of the disease. Here, we present a case of ocular involvement with West Nile virus, highlighting the typical ocular findings.

Case report

An 80 year old man convalescing in a nursing home from neurological complications of recently acquired West Nile virus meningoencephalitis presented with bilateral visual loss of unspecified duration. The patient had been hospitalised 4 months previously for serologically confirmed West Nile virus encephalitis. His infectious course was complicated by residual right sided paresis, dysarthria, and generalised mental status changes with dementia. Over the following months as he regained his mental faculties he complained to family members of decreased vision and central scotomas, worse in his left eye than right. His best corrected visual acuity at this time was 20/40 in the right eye and 20/60 in the left eye. The patient’s ophthalmic and medical histories were otherwise non-contributory. Biomicroscopic examination revealed normal anterior segments without inflammation and moderate nuclear sclerotic and cortical changes involving both crystalline lenses. Funduscopy examination revealed mild vitreous debris with moderately large areas of retinal pigment epithelial and choroidal atrophy in the posterior segment (fig 1A and B, right and left eyes, respectively) in addition to atrophic and pigmented chorioretinal foci throughout the retinal periphery (fig 2A and B, right and left eyes, respectively).

Over the next 3 months the patient developed problems with his activities of daily living at night and glare with lighting. Subsequent examination revealed progression of the lenticular changes and the patient was referred for cataract extraction. He returned 3 months later after uneventfully cataract surgery. He was not on any medication at this time. Best corrected visual acuity measured 20/30 in the right eye and 20/40 in the left eye. Normal anterior segments without inflammation and well placed posterior chamber intraocular lenses were noted. The vitreous debris persisted and his funduscopy examination was without change bilaterally. Examination 6 months later and approximately 16 months after initial West Nile virus infection demonstrated stable ophthalmic findings and visual acuity.

Comment

Although ocular symptoms associated with West Nile virus were first reported in 1996, ocular findings in West Nile virus infection were first described in the medical literature soon after the West Nile virus epidemic in North America in 2002.8 Initial reports described analogous clinical findings consisting of mild anterior segment inflammation, vitritis, and discrete nummular outer retinal/choroidal lesions which were often linear in distribution and varied in appearance from “creamy whitish-yellow” to atrophic with various degrees of pigmentation.8–10 Mild retinal haemorrhage was also occasionally present. Fluorescein angiography revealed these “target” lesions to be hypofluorescent centrally and hyperfluorescent peripherally. Leakage from the optic nerve is sometimes present as optic neuritis and papilloedema may be associated with contiguous central nervous system involvement.11 Later reports confirmed these findings and suggested that active lesions associated with vitritis may appear “creamy” in nature eventually progressing to foci of well circumscribed chorioretinal atrophy as the disease becomes inactive and subsequently becoming more prominent with time.12–14 Oclusive vasculitis without choriretinal findings has also been noted in an isolated case.15 Various ocular inflammatory and infectious processes such as toxoplasmosis and juvenile rheumatoid arthritis have been associated with periods of recurrence and
exacerbation after intraocular surgery. This highlights an important issue with regard to West Nile virus infection as the risk for neuroinvasive disease is higher for people 50 years of age and older, many of whom are currently or soon will be candidates for cataract extraction. Our patient did well with routine postoperative care and surveillance after uncomplicated cataract extraction in an eye previously affected by West Nile virus chorioretinitis. The eye remained quiescent without evidence of uveitis or reactivation of previously affected fundus lesions. Although surveillance would be recommended for these patients, our findings suggest that chorioretinitis associated with West Nile virus appears to be an acute self limited process without residual sequelae after subsequent intraocular surgery.

Swimming goggles suck
We present a complication arising from the use of swimming goggles in a patient with glaucoma drainage blebs.

Figure 1 (A) (B) Right eye at 4 months postoperatively showing corneal dellen and nasal bleb extension (A) and the adjoining isthmus (B) with arrows at each end. (C) Regression of the right accessory bleb after needling, 5-fluorouracil, and topical steroids. (D) Left eye at 7 months postoperatively with smaller and slightly inflamed nasal accessory bleb. (E) Pressure transducer setup measuring “intragoggle” pressure using AD Instruments Powerlab (www.adinstruments.com) and IOP transducer (gold disc). (F) Transducer recording showing several goggle applications (positive pressure, “+” labels) and the transient negative pressure spikes produced on removing them (“−” labels). In area 1 of the trace, the goggles were overtight and in area 2 they were comfortable.

Case report
A 73 year old white man with poorly controlled primary open angle glaucoma underwent routine trabeculectomy with adjunctive 5-fluorouracil to the right eye, followed by the same procedure to the left eye 6 weeks later. Preoperatively the intraocular pressures were 28 mm Hg bilaterally and cup-disc ratios were 0.95 right, 0.8 left. Early postoperative intraocular pressure (IOP) in the right eye was low (5 mm Hg at weeks 2 and 6), but uncomplicated. The recovery of the left eye was uneventful, and at 3 months the IOPs were 10 mm Hg right eye, 12 mm Hg left.

However, at 4 months the patient presented with discomfort and redness in the right eye. A large extension of the bleb had formed at the nasal limbus, with an associated corneal delen (fig 1A and B). The IOPs were 28 mm Hg bilaterally and cup:disc ratio was 0.95 right, 0.8 left. Early postoperative intraocular pressure (IOP) in the right eye was low (5 mm Hg at weeks 2 and 6), but uncomplicated. The recovery of the left eye was uneventful, and at 3 months the IOPs were 10 mm Hg right eye, 12 mm Hg left.

With this in mind, we set out to investigate the pressure changes occurring in the mask space during scuba diving. This is a rather different system as the nose is included in the mask, allowing the pressure to be equalised by exhaling through the nose. The eye and periorbital structures can be subjected to significant negative pressures if this is not done, but the duration is usually limited by this pressure gradient acting across the tympanic membrane, causing pain and prompting the diver to ascend or equalise. Ocular barotrauma can result in subconjunctival haemorrhage and chemosis, and it has been recommended that patients wait a minimum of 2 months after glaucoma filtering surgery before resuming scuba diving. We do not believe patients who have undergone trabeculectomy need to cease swimming, but they should be aware that goggles may be able to produce excessive negative pressure if they form a very tight seal.

Comment
Previous reports of barotrauma sustained while wearing overtight goggles include succion petechiae and changes in the eyelid skin, but we are not aware of any information concerning the effects of swimming goggles on glaucoma drainage blebs. When goggles are applied, firm pressure displaces a small volume of air and creates a negative “intragoggle” pressure, the basis by which a seal is maintained. In a person who has undergone trabeculectomy, an increase in the transconjunctival pressure gradient could open up a weakness in the perimeter of the bleb and cause it to extend in the direction of least resistance.

Other experimental work has examined the pressure changes occurring in the mask space during scuba diving. This is a rather different system as the nose is included in the mask, allowing the pressure to be equalised by exhaling through the nose. The eye and periorbital structures can be subjected to significant negative pressures if this is not done, but the duration is usually limited by this pressure gradient acting across the tympanic membrane, causing pain and prompting the diver to ascend or equalise. Ocular barotrauma can result in subconjunctival haemorrhage and chemosis, and it has been recommended that patients wait a minimum of 2 months after glaucoma filtering surgery before resuming scuba diving. We do not believe patients who have undergone trabeculectomy need to cease swimming, but they should be aware that goggles may be able to produce excessive negative pressure if they form a very tight seal.

Immune recovery disease: a case of interstitial keratitis and tonic pupil following bone marrow transplantation

Immune recovery disease results from an immunological response to circulating viral antigens in the host after bone marrow transplantation (BMT) mediated immune reconstitution. It may also occur after successful antiretroviral therapy in patients with HIV and AIDS. We report a case of a child with severe combined immune deficiency (SCID) and systemic varicella zoster virus (VZV) infection who developed interstitial keratitis and a tonic pupil after BMT.

Case report

An 8 month old male infant was referred to the ophthalmology clinic at Great Ormond Street because of suspected congenital glaucoma. The past ophthalmic and family history were unremarkable. The child was born with multiple congenital anomalies of the lower limbs which included bilateral tibal deficiencies, and an extra lateral epinovarous of the right foot.

The child had a known history of disseminated varicella infection caused by SCID (fig 1). On examination it was noted that he had a generalised vesicular rash throughout his body extending to his eyelid margins. The eyes were white with clear corneas and he was alert, fixing and following well with full extraocular eye movements. Both pupils were reactive to light and there was no evidence of post-terior synechiae (fig 3). A diagnosis of a right tonic pupil was made.

At the most recent review, 6 months following BMT he had clear corneas centrally in both eyes with some persistent peripheral stromal vessels, and a right tonic pupil. Unaided visual acuity was 0.60 logMAR with both eyes using the Cardiff acuity test (Keeler Ltd, Windsor, UK). There was a left fixation preference and amblyopia therapy was commenced with occlusive patches.

Currently, the child has an ongoing mild chronic graft versus host disease affecting the skin and intestine which is controlled with low dose systemic steroids. His systemic medications also include aciclovir 120 mg four times daily.

Comment

Severe combined immune deficiencies (SCID) are a rare heterogeneous group of disorders characterised by severe T cell and B cell deficiency with low or absent antibody levels. They usually manifest in the first months of life with severe and recurring infections leading to death often by the age of 2 years.

Since 1968 these diseases have been successfully treated with haemopoietic stem cell transplantation. Varicella infection has been associated with severe immune dysfunction following BMT and it has been shown that severe disseminated varicella infection causes ocular disease that mimics the sequelae of herpes zoster ophthalmicus. In the adult population, the commonest cause of interstitial keratitis is HSV infection whereas varicella infection is considered a rare cause. In children, although varicella infection is extremely common, ocular complications of this disease are rare.

If keratitis develops in association with a childhood viral exanthem it is important to consider a number of possible infectious agents such as HSV, EBV, mumps, syphilis, Lyme disease, or tuberculosis in the differential diagnosis. In this setting, other documented complications in association with SCID include bilateral viral endophthalmitis, CMV retinitis, and optic neuritis. In this case the history and the physical findings were highly suggestive of the diagnosis and were confirmed by PCR testing. As far as we are aware this is the first case of varicella...
associated interstitial keratitis and a tonic pupillary reaction from a nascent immune system in response from a nascent immune system in the recipient—an example of immune recovery disease.

There is experimental evidence to support this as it has been shown that whole lymphocyte and splenocyte transfer leads to herpetic simplex keratitis in SCID mice. In other words SCID mice reconstituted with T lymphocytes of the CD4+ phenotype developed subsequent corneal lesions in relation to HSV infection. Conversely Mercadal et al had shown that unconstitution SCID mice remained lesion free when infected with HSV. This suggests that herpetic simplex keratitis is a T-cell mediated immunopathological reaction to virus in the cornea. In our case the corneal changes occurred following bone marrow reconstitution. Before BMT the CD3+ CD4+ count was 0.4 x 10^9/l but 7 weeks following BMT the CD3+ CD4+ count was 0.47 x 10^9/l. The corneal changes become apparent at about 4 weeks after BMT. We believe that our case illustrates a similar mechanism in the human model in relation to varicella infection.

The tonic pupil developed as a consequence of a post-viral ganglionitis affecting the ciliary ganglion and the short posterior ciliary nerves, a rare but previously described complication of varicella infection. Other reported cases of ophthalmic immune recovery disease include a case of varicella zoster virus reported cases of ophthalmic immune recovery disease in the child with severe combined immunodeficiency. Arch Ophthalmol 1994;112:1280–1.

Ocular macular dystrophy in an 11 year old boy

Ocular macular dystrophy (OMD) is an inherited retinal dystrophy characterised by a progressive decline of visual acuity without visible fundus abnormalities. In these patients, the fluorescein angiograms and conventional full field electroretinograms (ERGs) are normal, but the amplitudes of the foveal macular ERGs and multifocal ERGs are significantly reduced but only in the central retina. The age at the onset of symptoms in OMD patients is relatively old, and the first visit to the hospital is aged 20 years or more with the youngest being 16 years old. Here, we present an 11 year old boy who was diagnosed as having OMD because of the results of electrophysiological and psycho-physical tests.

Case report

An 11 year old boy was referred to our hospital with a complaint of progressive decline of vision in both eyes. His corrected visual acuity was 20/25 in both eyes at 6 years of age, but had decreased to 20/33 at 10 years of age. Family history revealed no members to have any eye diseases. At the initial examination, his visual acuity was 20/40 right eye and 20/33 left eye with −3.0 dioptres (D) in both eyes. The fundus examination and fluorescein angiograms were normal (fig 1). The peripheral visual fields were intact but a relative central scotoma was detected at the 1:2 target within 10 degrees in both eyes. A moderate red-green defect was found on the Ishihara pseudosochromatic plates, Hardy-Rand-Rittler pseudosochromatic plates, and Farnsworth-Munsell 100 hue test.

The amplitude of full field ERGs were within the normal range for both rod and cone components (fig 2A). However, focal macular ERGs with 5, 10, and 15 degrees stimulus spots were severely reduced and essentially absent (fig 2B). The multifocal ERGs demonstrated a loss of local responses in the central retina (fig 2C).

Psychophysical rod and cone sensitivity was performed on his right eye with 31 test points across the 60 degree horizontal meridian using a previously described method. The cone sensitivities were severely affected in the central retina but fell within the normal range in the periphery (fig 2D). The rod sensitivities were at the lower borderline at almost all locations tested (not shown).

At present (August 2003, 13 years old), his acuity has decreased to 20/50 in both eyes, but his fundus still remain normal in both eyes.

Comment

This boy had a progressive decrease of visual acuity in both eyes, and his fundus examinations and fluorescein angiograms were completely normal. The amplitude of the conventional full field ERGs were also within the normal range for both rod and cone components. However, focal macular cone ERGs and multifocal ERGs were severely reduced in the central retina. Results of psychophysical perimetry showed a reduction of cone sensitivity but only in the central retina. These findings are consistent with the clinical characteristics of OMD which we have previously reported.

OMD in children is very rare. In our 42 consecutive OMD patients seen at the Nagoya University Hospital from 1988 to 2003, the age at initial visit to the hospital ranged from 16 to 74 years (mean 45.8 years), and 95.2% of patients visited the hospital at 20 years old or more. To the best of our knowledge, this boy is the youngest case with OMD reported anywhere.

We would like to emphasise that OMD can be found even in children. Because the fundus examination and full field ERGs are normal in these patients, these children are apt to be misdiagnosed as optic nerve disease, central nerve disease, or psychological
disorders. Focal or multifocal ERG techniques are the only key to diagnose this rare type of macular dystrophy.

Pseudomonas aeruginosa microbial keratitis secondary to cosmetic coloured contact lens wear

Cosmetic coloured contact lenses are worn to give the appearance of a different or unusual eye colour and about 60,000 people in the United Kingdom obtain these types of contact lenses through eye care professionals.1 A subset of these lenses—those with no optical power (“plano” coloured lenses)—falls outside legislation designed to restrict the sale of contact lenses to suitably qualified professionals. We report a severe case of microbial keratitis caused by Pseudomonas aeruginosa which has resulted in lasting visual impairment in a patient obtaining cosmetic coloured contact lenses from a fashion shop rather than through an eye care practitioner.

Case report
An 18 year old south Asian male student presented in December 2003 with a 2 day history of a foreign body sensation in his left eye. One day before presentation the eye had become slightly red. He had commenced the use of Brolene eye drops which had been purchased from a large chain supermarket. The eye then became painful with eyelid swelling and he presented to the local district general hospital the following day. He was diagnosed with a corneal ulcer and referred to our institution.

Figure 1 Fundus photographs (upper) and fluorescein angiograms (lower) of the 11 year old boy.

Figure 2 Results of conventional full field ERG, focal macular cone ERG, multifocal ERG, and cone perimetry in our patient. Full field ERGs, focal macular cone ERGs, multifocal ERG, and cone perimetry are recorded with previously reported methods.2–5

References
No counselling was provided at the point of purchase regarding a hygiene routine, care of lenses, or possible complications associated with their use. He wore the lenses 12 hours per day, 7 days per week without any overnight use. The lenses were designed to make the eye appear grey or blue (patient’s natural eye colour was brown). There was no past medical or ocular history of note including amblyopia.

On examination the unaided vision was 6/6 in the right eye and 6/36 in the left eye. The left eye demonstrated a mid- to peripheral corneal infiltrate in the 4 o'clock position with overlying 2.4 mm diameter ulcer, and surrounding stromal swelling (fig 1). There was a 0.5 mm height hypopyon. The intraocular pressure was within the normal range. The right cornea demonstrated a very small peripheral infiltrate with no significant anterior chamber reaction. Both posterior segments were unremarkable. A corneal scrape was performed with the Gram stain demonstrating a small quantity of neutrophils and Gram negative bacilli. Ofloxacin 0.3% drops were commenced every hour to the left eye. The peripheral infiltrate resolved with the corneal epithelial healed by day 10. Topical prednisolone 0.5% was commenced on day 4. A more central mid stromal corneal infiltrate encroaching on the visual axis developed on day 1 after admission and has gradually become less prominent during follow up over 3 months (fig 2) although the visual acuity remains reduced at 6/36. *Pseudomonas aeruginosa* was grown from the corneal scrape, sensitive to ciprofloxacin, ofloxacin, gentamicin, and ceftazidime. The right eye was not scraped, responded well to topical ciprofloxacin drops, and did not develop any scarring. The contact lenses and their cases were also investigated as there was a high degree of suspicion that clinically they would be contaminated. All grew *Pseudomonas aeruginosa* with a sensitivity profile identical to the corneal scrape specimen. Mixed coliform growth was also noted also in one of the contact lens cleaning solutions.

Comment

The use of cosmetic coloured plano contact lenses, sourced via non-professional suppliers is becoming increasingly common and fashionable. Their use over the past 12 months is becoming increasingly common and fashionable. Their purchase is currently possible from non-eye care professional retailers without offering the lens to the purchaser. Demonstrating fitting on themselves before exchanging between wearers and of sales staff reporting the lenses being shared and "afocal" contact lenses are not included in legislation should be passed stipulating that contact lenses. Plano (or "afocal") contact lenses are not included in the united states.1 *Pseudomonas aeruginosa* microbrial keratitis with vision loss requiring elective penetrating keratoplasty, presumed herpes simplex related corneal scarring causing legal blindness, acute iridocyclitis, corneal hypoxia, microcyctic oedema, punctuate keratoconus, corneal abrasions, and giant papillary conjunctivitis were all documented.

In the United Kingdom, the Opticians Act 1989 states that a person who is not a registered medical practitioner or registered optician shall not fit contact lenses. Plano (or "afocal") contact lenses are not included in this act because they have no optical power. The General Optical Council has received reports of these lenses being shared and exchanged between wearers and of sales staff demonstrating fitting on themselves before offering the lens to the purchaser.2 In November 2000 the General Optical Council submitted recommendations to the Department of Health arguing that primary legislation should be passed stipulating that the fitting and sale of plano contact lenses should also fall within the terms of the act. On 28 October 2003 Mr John Robertson, MP for Anniesland, Glasgow, moved a bill to amend the Opticians Act 1989 to include plano contact lenses in the restrictions already placed on the sale of other contact lenses.3 This case report highlights the potential complications of these lenses and supports legislation restricting their sale.

4 Cosmetic contact lenses draft explanatory notes.
5 The United Kingdom Parliament. Bill moved by Mr John Robertson (Glasgow, Anniesland): Non-Prescription Contact Lenses. 28 October 2003:

Severe proliferative retinopathy in a patient with advanced muscular dystrophy

The patient is a 25 year old white man with Duchenne muscular dystrophy (DMD), complicated by respiratory failure requiring ventilatory assistance and impaired cardiac function. His ocular complaints were “floaters” and decreased vision over the preceding 6 weeks. He had no history of ocular disease or trauma. The patient’s level of alertness was reported to routinely fluctuate but no new neurological findings were present. The best corrected visual acuity was count fingers in the right eye and 20/70 in the left eye. The intraocular pressures were 14 and 8 mm Hg. The anterior segment examination was unremarkable with no neovascularisation of the iris or angle. Biomicroscopy revealed bilateral vitreous haemorrhage. Indirect ophthalmoscopy showed the retinal periphery to be attached in both eyes. The optic discs and maculae were partially obscured by haemorrhage. Fluorescein angiography revealed delayed filling and venous beading in both eyes, without central or branch, vascular occlusion. Hyperfluorescence, consistent with neovascularisation, was present along the temporal vascular arcades and at the optic discs. Fundus photography corroborated the angiographic findings (see figs 1 and 2).

Indirect laser with scleral depression resulted in full treatment of retina outside of the vascular arcades. Treatment appeared to have little effect on neovascular progression. Overwhelming anaesthetic risk prevented intraocular procedures. Both eyes progressed to subtotal traction retinal detachment and counting fingers vision.

Comment

The working diagnosis was retinal ischaemia secondary to hypoperfusion or pan-microvascular occlusive disease. The cardiac ejection fraction was 20% of predicted; the forced vital capacity was 14% of predicted and the forced expiratory volume in 1 second was 15% of predicted. We believe that cardiopulmonary compromise was a primary

Figure 1 Colour fundus photograph of the right eye depicting venous beading (arrow), neovascularisation of the disc (arrowheads), and vitreous haemorrhage.

Figure 2 Residual central corneal infiltrate at 1 month after presentation.
greater damage to the ganglion cell layer 

suffering from the Dp71 isoform of dystrophin suggest that absence of dystrophin is not 

routinely associated with proliferative retino-

als and around retinal vessels. Deficiency 

dystrophin produces abnormal transmis-

mice. 7 Therefore, dystrophin may be involved 

in the regulation of ischaemic processes in 

the retina. Cardiopulmonary assist is not 

routinely associated with proliferative retino-

pathy in adults. Retinal neovascularisation is 

not prevalent in the Duchenne population, 

suggesting that absence of dystrophin is 

not sufficient to induce neovascularisation alone. 

In summary, rapidly progressive, bilateral 

proliferative retinopathy may be associated 

with DMD in the presence of severe cardio-

pulmonary compromise. Whether an absence 

dystrophin contributes directly or indirectly 

is unknown but consideration of the possibility may lead to novel insights into the 

development of pathological retinal neovas-

cularisation. The visual prognosis with late 

presentation in this setting is uncertain 

despite full panretinal photocoagulation. 

Patients with advanced DMD may benefit 

from periodic fundus examination as it is not 

known whether early treatment has the 

potential to alter prognosis.

Bilateral decompression retinopathy after orbital decompression surgery

Depreevation of retinal haemorrhages that typically occur 
after glaucoma filtration surgery. 7, 8, 9

Orbital decompression is a common sur-

gery performed to treat patients with thyroid 

related orbitopathy for functional or cosmetic 

indications. 10, 11 Many complications have been 

described with the surgery, but this surgery has 

never been associated with retinal haem-

orrhages.

We describe a case of a 70 year old woman, 

who developed bilateral retinal haemor-

rhages after staged bilateral orbital decom-

pression surgeries.

Case report

A 70 year old woman with the diagnosis of 
euthyroid Graves’ disease was referred 

because of severe proptosis. Past ophthalmic 

history revealed two previous strabismus 
surgeries. Past medical history was unre-

markable with no history of diabetes or 

cardiovascular disease, also she was not 

taking aspirin or any other blood thinning 

medications.

Ophthalmic examination showed visual 

acuity of 20/20 in each eye. Both orbits were 

moderately firm to retropulsion. IOP was 

within normal limits in primary gaze (14, 

19 mm Hg) and slightly elevated in upgaze 

(17, 26 mm Hg). There were limitations 
in upgaze and lateral gaze in both eyes as well 
as upper and lower lids retractions. There was 
a mild degree of lagophthalmos with expo-

sure keratopathy. Funduscopic was normal 

and did not show any evidence of micro-

vascular disease or retinal haemorrhages.

Hertel measurements were 22 mm on the 

right and 23 mm on the left. Computed 
tomography scan showed enlargement of the 

extraocular muscles.

She underwent bilateral orbital decom-

pression surgery on the left side, including 
depreevation of retinal haemorrhages both in deep and 

superficial layers of the retina. VA 20/25. 

Lower image) Fluorescein angiography, left eye, late frame showing blocked fluorescence 

from retinal haemorrhages.

Figure 1 Fundus photograph (upper image), 

left eye, 4 days after orbital decompression 
surgery on the left side showing scattered 

retinal haemorrhages both in deep and 

superficial layers of the retina. VA 20/25.

www.bjophthalmol.com
Decompression retinopathy is a rare complication that may occur after glaucoma filtration surgery. It is associated with scattered retinal haemorrhages concentrated in the posterior pole. While it is more common in patients with marked elevated preoperative intraocular pressure and after acute decrease of IOP, the haemorrhages may be diffuse, both in deep and superficial layers of the retina, and may even show white centres when first observed. Retinal haemorrhages associated with ocular decompression appear to be relatively benign and usually resolve within weeks to months with no effect on visual acuity or intraocular pressure. A gradual decrease of IOP preoperatively and intraoperatively is recommended in order to avoid this complication.

Decompression retinopathy has not previously been described as a complication of orbital decompression surgery. Our patient had a relatively tight orbit with restrictive strabismus and marked enlargement of the extraocular muscles. Significant force was required to retract the globe to achieve exposure of the medial and deep lateral orbital walls. Retraction was frequently relaxed to assure perfusion of the retina. We hypothesise that the marked intraocular pressure fluctuation that occurs during these surgical manoeuvres may have contributed to the retinal haemorrhages. It may also be that rapid decrease in retrobulbar pressure has caused ocular hypotony and retinal haemorrhage.

Figure 1  (A) Goldmann perimetry revealed a nasal visual field defect 4 months after ICG assisted peeling of ILM for ERM. Visual field defect testing was also performed 8 months after the surgery, which demonstrated no remarkable change. (B) Fundus photograph taken 4 months after the surgery shows that the optic disc rim appeared to have lost colour without being associated with any cup or rim changes typically seen in glaucoma. The appearance of the optic disc remained unchanged during our 8 month follow up. (C) Infrared fundus photograph taken 8 months after the surgery with an ICG filter set. Residual ICG was evident at optic disc rim and the nerve fibre. The fluorescent intensity and distribution of residual ICG did not change remarkably during our 8 month observations.

Figure 2 Fundus photograph (upper image), right eye, 4 days after orbital decompression surgery on the right side showing scattered posterior pole retinal haemorrhages. Note the haemorrhage present in the fovea. VA 20/160. (Lower image) Fluorescein angiography, right eye, late frame showing blocked fluorescence from retinal haemorrhages.

Retinal nerve fibre layer damage after indocyanine green assisted vitrectomy

Recently, indocyanine green (ICG) has been used to stain and visualise the internal limiting membrane (ILM) during vitrectomy. Some case series showed that visual field defects on the nasal side can occur after the surgery through unknown cause. Here, we report a case in which nasal visual field defects occurred after ICG assisted ILM peeling for epiretinal membrane (ERM). Detailed examination revealed that the superior and inferior retinal nerve fibre is severely damaged in this case.

Case report

A 60 year old woman who received ICG assisted ILM peeling for ERM in her right eye was referred to our hospital. The preoperative best corrected visual acuity (BCVA) was 20/60 in the right eye. According to the referring ophthalmologist, 25 mg of ICG (Diagnostreen; Daiichi Pharmaceuticals) was dissolved in 10 ml of distilled water, which was further diluted by a viscoelastic material (Healon; Pharmacia) to give 0.16% ICG solution. To stain ILM, ICG was injected into an air filled eye and the dye was washed 2 minutes later. An air infusion cannula was placed at the temporal side. There was no complication during the surgery. Seventeen days after the operation, she noticed nasal visual field loss, which got worse 22 days after the surgery. Sixty days after the surgery, she was referred to our hospital. At the initial visit, the BCVA was 20/25 in the right eye. Goldmann perimetry revealed a nasal visual field defect (fig 1A). In the right eye, a relative afferent pupillary defect was found. Ophthalmoscopic examination and fluorescein angiography showed no abnormalities. The optic disc rim appeared to have lost colour without being associated any cup or rim changes typically seen in glaucoma (fig 1B). Residual ICG was evident at the optic disc and along the nerve fibre (fig 1C). The nerve fibre staining was most evident in the superior and inferior quadrants. ICG angiography revealed ICG staining of the optic disc and superior and inferior nerve fibres, but no other abnormalities. Full field electroretinogram (ERG) and multifocal ERG (VERIS science ver3.8, EDI) revealed no abnormalities. The results of visual evoked potential testing were also non-remarkable.

During our 8 month follow up period, there was no significant change in the visual field defect and the distribution of the residual ICG. Scanning laser polarimetric analysis (GDx VCC, Laser Diagnostic Technologies, Inc, San Diego, CA, USA) performed 8 months after the surgery showed profound nerve fibre loss around the disc, especially evident at superior and inferior quadrants (fig 2).

Comment

In this case, an air infusion cannula was placed at the temporal side and Goldmann perimetry showed nasal visual field defects. Thus, the dehydration injury to the retina during air-fluid exchange, which is observed at the opposite side of the cannula, is unlikely to be the cause of this visual field defects. Optic neuropathy unrelated to the use of ICG may be considered as a differential diagnosis. Howevver, this visual field damage is not typically seen in optic neuropathy and may be rather associated with ICG, based on...
Competing interest: none.

by scanning laser polarimetry.

References

Recent clinical findings.

Retinal damage was not evident by morphological, angiographic, and functional analysis. However, it was evident that the nerve fibres are damaged in this patient. Although the direct causal relation cannot be proved, it is highly likely that the damage to the nerve fibres was caused by the ICG because of the remarkable correspondence of the distribution pattern of ICG and the nerve fibre defects. This is also supported by our experimental findings that ICG showed neurotoxicity at concentrations lower than clinically employed. To our knowledge, this is the first report of ICG induced retinal nerve fibre damage assessed by scanning laser polarimetry.

Figure 2 The results obtained from the GDx-VCC from the right (top) and left (bottom) eyes taken 8 months after the surgery. The left column shows the retardation image. The centre column shows the results from analysis. The navy, blue, yellow, and red points represent significant loss of nerve fibre layer, p<5%, 2%, 1%, and 0.5%, respectively. The right column shows that the general double hump pattern is evident in the left eye but is lost in the right eye.

Worldwide clinical trials for new technique for early detection of eye disease

A unique new non-invasive technique for high resolution optical imaging of the eye is receiving global acclaim. The technique, pioneered by the University of Kent, is funded by the Toronto-based company, Ophthalmic Technology Inc (OTI). The University’s Applied Optics Group is currently working with university hospitals in New York (USA), Osaka (Japan), Asahikawa (Japan), Amsterdam (Netherlands) and Milan (Italy) to carry out preliminary clinical trials. By combining two high-resolution imaging technologies, the new technique provides doctors with 3-D images of the retina, macula and the optic nerve. Such high resolution images provide clinicians with capabilities for early diagnosis and treatment of common ocular diseases such as glaucoma, diabetes and age-related macula degeneration. OTI is planning in the near future to extend the clinical research to other leading university medical centres in Japan, USA and Europe.

Professor Adrian Podoleanu explained: ‘At Kent we created a very cost effective imaging system which simultaneously produces optical coherence tomography (OCT) and scanning laser ophthalmoscope (SLO) images. Its early potential was immediately realised by OTI, who commissioned the assembly of several prototypes to be tested in different clinics worldwide before embarking on commercial exploitation of the invention.

The clinical investigators together with the Kent team have jointly published in international medical publications and presented at clinical and scientific conferences over 50 publications and presentations related to this research.
