Echographic features of a case of malignant intraocular medulloepithelioma

Intraocular medulloepithelioma is a rare embryonal neoplasm, usually presenting in the first decade of life as a unilateral, cystic ciliary body mass. Histologically, medulloepithelioma is classified as non-teratoid (a pure proliferation of medullary epithelial cells) or teratoid (containing heteroplastic elements such as hyaline cartilage, skeletal muscle, or neural tissue). Either group can be subclassified as benign or malignant, the latter showing evidence of poor differentiation, increased mitotic activity, and local invasion with or without extracanal extension.

We report the progressive echographic findings in a case of malignant intraocular medulloepithelioma. Echographic examination, by B-scan (10 MHz probe) and high resolution anterior segment scan (20 MHz probe), was performed during two examinations under anaesthesia (EUA), using the 13 system.

Case report

An 18 month old girl presented with a distorted pupil apparently following a fall downstairs some 4 weeks previously. Her right pupil was displaced inferotemporally, with a localised area of ectropion uveae and underlying segmental lens opacity. An urgent EUA confirmed the clinical findings. The retina and ora serrata were normal on fundoscopy but there was the vague suggestion of a subtle whitish pars plana abnormality inferotemporally. Visualisation of this area was however hampered by the lens opacity. B-scan was normal but high resolution scan showed an inferotemporal peripupillary iris cyst with irregular thickening of the peripheral iris. The ciliary body appeared normal but a triangular opacity of moderate reflectivity arose from the inferotemporal pars plana and extended along a thickened anterior hyaloid face (fig 1). In the absence of a definite mass the tissue changes were thought possibly to be secondary to trauma, perhaps of a penetrating nature. It was decided to manage her conservatively with an initial period of observation and occlusion therapy.

Unfortunately, she was lost to follow up and re-presented 4 months later with a right mature cataract. A repeat EUA was performed and B-scan now showed a partial posterior vitreous detachment with cellular vitreous. High resolution scan showed extensive increased irregular echoes of variable reflectivity extending from the pars plana to the ciliary body and along the anterior hyaloid face to the posterior lens. Small echolucent areas were present as well as one area of hyper-reflectivity inferotemporally. Although there was no absolute shadowing posterior to this hyper-reflective area, it remained highly reflective at low gain suggesting possible cartilage (fig 2A–C). Lens aspiration was performed revealing a dense, vascularised ciliary membrane and underlying white fibrous tissue circumferentially around the pars plana and ciliary body though no distinct mass. Inferotemporally this structure was cystic with an area of hard chalky tissue, corresponding to the bright echo on scan, which was again thought probably to represent cartilage. A diagnosis of possible medulloepithelioma was made and confirmed on subsequent histological examination of tissue biopsies and vitreous cytology. Unfortunately, during surgery she developed an inferotemporal retinal dialysis requiring vitrectomy and inevitably some retrolenticular tissue was lost to further histological analysis during this procedure.

Subsequent enucleation and extensive histological examination of the globe confirmed the diagnosis of malignant medulloepithelioma, although no heterologous elements could be identified in the available tissue.

Comment

Limited information exists regarding the echographic features of medulloepithelioma. We had the rare opportunity of examining a case of malignant medulloepithelioma by B-scan and high resolution scan at both early and later stages of development, showing significant progression of the condition. Our case presented with a pupil abnormality, localised segmental cataract and probable early cyclitic membrane arising from the pars plana but not with a typical ciliary body mass. Development of a cyclitic membrane is a recognised feature associated with medulloepithelioma. We have demonstrated the value of high resolution echography in such cases particularly demonstrating early changes when little was clinically evident. Our case demonstrates that, even in the absence of a ciliary body mass, the suggestion of early or unusual retrolental membrane should alert one to the possible diagnosis of intraocular medulloepithelioma.
Drug induced autoenucleation with resultant chiasmal damage

Self enucleation or “oeedipism” is a rare form of self mutilation occurring with paranoid delusions, either as a result of a drug related toxic psychosis or in functional psychoses, such as schizophrenia. It is most often described in acutely psychotic patients, who have religious or sexual delusions.

We report a case of self enucleation of a right eye in a 19 year old male—induced by drug psychosis. The force of autoenucleation traumatised the chiasm resulting in a left temporal field defect. Only two cases of contralateral field defect secondary to chiasmal damage have been reported in the literature. Many drugs are known to cause hallucination leading to self mutilation.

Deliberate self harm (DSH) is a well known entity which varies from mild (skin picking and hair pulling) to severe forms of self mutilation like self amputation and picking and hair pulling) to severe forms of self mutilation after self enucleation, including intracranial bleeding, optic chiasmal injury, and bone fractures.

Self enucleation or “oeedipism” is a rare entity which requires operative reconstruction of the orbit, and also neurological monitoring to identify and treat any possible intracranial complications. The other eye should be observed for possible sympathetic ophthalmia which may occur because of residual uveal tissue in the socket. Visual field of the remaining eye must be performed in the acute phase, as field loss secondary to chiasmal trauma or severe traumatic optic neuropathy may occur and may be irreversible.

Drug induced autoenucleation in drug-related psychosis

This report presents a rare case of a self enucleation of the right eye in a young man. This severe trauma resulted in loss of vision in the right eye and partial visual field loss in the other eye. Avulsion of the optic nerve was found in the right eye. The left eye showed no evidence of ischaemia or sympathetic ophthalmia. The visual field defect of the left eye resulted from traumatic severance of the right optic nerve causing secondary chiasmal damage. There were no intracranial complications.

Life threatening complications may result from self enucleation, including intracranial or subarachnoid haemorrhage, cerebrospinal fluid leakage, and bacterial meningitis.

Radiographic imaging is required to exclude intracranial bleeding, optic chiasmal injury, and bone fractures.

Visual field of the remaining eye must be performed in the acute phase, as field loss secondary to chiasmal trauma or severe traumatic optic neuropathy may occur and may be irreversible.

Thus cases of severe optic neuropathy and chiasmal damage are rarely reported, this may be due to lack of symptomatology and failure to perform field testing. The importance of visual field analysis cannot be overemphasised, because of the potential implications for affected patients.

Repeted intravitreal injection of triamcinolone acetonide for diffuse diabetic macular oedema

Recent studies have suggested that intravitreal triamcinolone acetonide may be a treatment option for diffuse diabetic macular oedema. Since the duration of the effect of an intravitreal application of triamcinolone acetonide lasts between 4 weeks and up to 9 months, the purpose of this study was to evaluate the effect of a repeated intravitreal injection of triamcinolone acetonide.

Case reports

The clinical interventional case series study included four patients with diffuse diabetic macular oedema who consecutively received a second intravitreal injection of about 20 mg triamcinolone acetonide 7.6 (SD 3.9) months (median, 6.7 months; range, 4.1–13.1 months) after the first injection, and for whom follow up was longer than 3 months. The second injection was carried out, since visual acuity had decreased again after an initial increase following the first intravitreal injection. Mean follow up after the second injection was 5.6 (SD 4.2) months (median 5.6 months; range 1–10.5 months). Mean age of the patients was 62.0 (5.8) years (range 56.8–67.8 years; median 61.7 years), refractive error ranged between a mean of −0.79 (SD 1.19) dioptres and +2.50 (1.38) dioptres. All patients were fully informed about! the experimental character of the therapy and had signed an informed consent. The ethics committee of the university had approved the study. All patients received an intravitreal injection of about 20 mg triamcinolone acetonide in 0.2 ml Ringer’s solution as previously described in detail.

After the first injection, visual acuity increased from 0.12 (SD 0.05) (range 0.08–0.20) to a maximum of 0.23 (SD 0.14) (range 0.10–0.40). Converting visual acuity measurements into the logarithm of the minimum angle of resolution (logMAR) showed a change in the minimum angle of resolution from 0.95 (SD 0.17) logMAR units to 0.71 (SD 0.29) logMAR units. After the second injection, visual acuity increased from 0.12 (SD 0.06) (range 0.08–0.20) to a mean maximal visual acuity of 0.18 (SD 0.06) (range 0.10–0.25). The maximum angle of resolution changed from 0.97 (SD 0.19) logMAR units to 0.77 (SD 0.17) logMAR units. All eyes increased in visual acuity. After the first injection, and after the second injection, respectively, intraocular pressure increased to values higher than 21 mm Hg in three eyes. For all of these eyes, intraocular pressure could be normalised by topical antiglaucomatous treatment.

Comment

The data of this study may suggest that the repeated intravitreal injection of about 20 mg of triamcinolone acetonide as treatment of diffuse diabetic macular oedema can be associated with a increase in visual acuity again in those patients who as “triamcinolone responders” showed an improvement in visual acuity after a preceding intravitreal injection of triamcinolone acetonide. It is in agreement with a previous study on repeated intravitreal injections of triamcinolone acetonide for exudative age related macular degeneration.

Papillary vasoproliferative changes in cat scratch disease

A 23 year old man presented with a 10 day history of floaters in both eyes, predominantly in the right. He denied a febrile illness and exposure to animals. General medical history was unremarkable. He was not taking any medication.

On examination his visual acuity was 6/4+1 in the right eye and 6/4 in the left eye. Anterior chambers were quiet in both eyes. Dilated retinal examination showed 2+ vitreous cellular activity in the right eye and 1+ in the left eye, as well as evidence of bilateral neuroretinitis. The right optic disc was swollen with large dilated tortuous vessels associated with marked gliosis. The lesion was surrounded by lipid exudate and an inferior preretal haemorrhage (fig 1). In the left eye, there was also a prominent sheathed arteriole superior to the fovea.

Fluorescein angiography in the early phase demonstrated the arterial aneurysmal vascular changes on the optic disc (fig 2). Significant leakage occurred in the mid-phase (fig 3). There was no evidence of retina arteriolar or venular occlusion.

Full blood count with differential, serum electrolyte, C reactive protein, and erythrocyte sedimentation rate results were normal. The serum IgG was slightly elevated (IgG 14.26 g/l, normal laboratory range 6.12–12.93 g/l) and the serum IgA and IgM levels were normal, with a normal serum electro- phoretic pattern. HIV serology was negative. Mantoux test, treponemal serology, antinuclear antibody, rheumatoid factor, and sarcoid results were also negative. An orbital computed tomography (CT) scan did not show significant abnormalities.

The diagnosis of cat scratch disease was confirmed by an elevated titre for Bartonella (Rockalana) henselae of 1:128 using the indirect fluorescent antibody test.

The patient was treated with 150 mg oral doxycycline twice daily and 100 mg oral rifampicin twice daily. The vitritis settled with prednisone. However the aneurysmal disc changes remained unchanged. At 1 year follow up his visual acuity was 6/6 in both eyes. The left eye subsequently developed marked papillary vasoproliferative changes at 12 months (fig 4).

Comment

Cat scratch disease (CSD) is typically a benign and self limiting illness, caused by Bartonella henselae bacteria (previously known as Bartonella quintana and B. elizabethae)

Treatment of recurrent orbital haemangiopericytoma with surgery and proton beam therapy

Orbital haemangiopericytoma is a rare, potentially malignant vascular tumour, which can affect any part of the orbit. The treatment of choice is complete surgical excision but because of its vascular nature and tissue friability during surgery this is frequently not achieved. Difficulties in correctly diagnosing this tumour preoperatively compound this problem. Incomplete excision is associated with increased risk of local recurrence and metastatic disease, which are reported to occur in up to 43% and 15% of cases respectively, and can take many years to become manifest. Treatment options for orbital recurrence include orbital exenteration, further attempts at complete excision, or local excision and adjuvant therapy with radiotherapy, brachytherapy, or chemotherap y. To our knowledge the use of proton beam therapy in controlling recurrent orbital haemangiopericytoma has never been described. We therefore report such a case.

Case report

A 61 year old woman presented with a second recurrence of a left medial orbital haemangiopericytoma 2 years following radical excision of the tumour via a transfrontal approach, and 14 years after initial excision. She was found to have non-axial proptosis of the globe associated with a soft tissue swelling at the medial canthus (fig 1). Her visual acuities were unchanged from initial presentation at 6/6 in the right eye and 6/9 in the left eye. She also had restriction of the left eye. She also had restriction of left eye motility. In the 7 years following her proton beam therapy serial magnetic resonance imaging (MRI) has revealed no further growth of the residual tumour mass (fig 2). She maintained a visual acuity of 6/6 in the left eye for 3 years following treatment but subsequently developed ischaemic optic neuritis reducing her acuity to 5/60.

Comment

This patient, having already undergone extensive orbital surgery on two occasions, was reluctant to consider a further procedure. Although there is evidence to support the use of adjuvant external beam radiotherapy after conservative surgery, it was felt that because of the size and location of our patient’s tumour, the dose required was likely to cause significant damage to surrounding structures. A decision was therefore taken to explore proton beam therapy as a potential adjuvant treatment for our patient, particularly as our department has gained experience with its use in the management of uveal melanomas. Following discussion with our colleagues at the Douglas Cyclotron, Clatterbridge Centre for Oncology, it was decided that owing to the relatively superficial location of the tumour, proton beam therapy would be a feasible option.

High energy heavy charged particle irradiation with proton beams offers several advantages over external radiotherapy. The particles have minimal scatter and can be collimated into small beams delivering maximal ionisation as they stop. This results in the phenomenon of the Bragg peak which is “modulated” with depth to produce a precise uniform dose volume. As the depth of penetration can be controlled, the radiation can be targeted almost exclusively at the tumour mass with minimal irradiation of surrounding tissues. The radiation dose of 50 Gy equivalent was chosen empirically and based on the normal dose used for the treatment of choroidal melanomas as there is no precedent in using this treatment for orbital haemangiopericytoma.

Unfortunately, this patient developed ischaemic optic neuropathy which is a recognised complication of proton beam therapy, particularly when more than 2 mm of optic nerve is irradiated at 30 Gy equivalent. Because of the size and location of our patient's tumour, there was a high risk of this complication occurring, as there would have been had external beam radiotherapy been used instead. Nevertheless, this report demonstrates that proton beam therapy can be effective in controlling recurrent orbital haemangiopericytoma.

Figure 1 (A) Before further local excision and proton beam therapy the left medial orbital swelling and lateral globe displacement is obvious. (B) 7 years after treatment the reduction in tumour mass is clearly visible.

orbital haemangiopericytoma and perhaps its use should therefore be considered as an adjuvant in the treatment of recurrent disease, particularly when the tumour is in a superficial location.

Bilateral surgically induced necrotising scleritis with secondary superinfection

Surgically induced necrotising scleritis (SINS) is a rare complication of ocular surgery that has been described after pterygium excision, cataract extraction, trabeculectomy, penetrating keratoplasty, strabismus surgery, and retinal detachment repair.1–3 We describe a rare case of bilateral necrotising scleritis complicated by a secondary polymicrobial infection following unaccomplished phacoemulsification and pterygia excision.

Case report
A 66 year old Samoan male, with type II diabetes, end stage renal disease, coronary artery disease, and gout underwent unaccomplished combined phacoemulsification and bare sclera pterygium excision (without antimetabolites) in the right eye, followed 1 month later by the same combined procedure in the left eye. Three weeks later, the patient developed severe right sided eye pain. An erythrocyte sedimentation rate was 98 mm in the first hour, and oral prednisone (80 mg/day) was initiated. A temporal artery biopsy was negative and prednisone was discontinued after 4 days of treatment. One week later, the patient developed left sided eye pain as well as a productive cough. Corneoscleral necrosis developed in the left eye and rapidly progressed to perforation.

On examination, the visual acuity was 20/200, the area of necrosis had enlarged and the pupil began to peak nasally. Systemic immune suppression was initiated with an intravenous pulse of 1 g of both cyclophosphamide and methylprednisolone. Within 48 hours of initiating immune suppression, granulation tissue began to fill the areas of necrosis and ocular pain subsided. Two months following presentation, while on a prednisone taper, the patient’s best corrected visual acuity was 20/40 right eye. He remained at light perception in the left eye.

Comment
We believe this complicated case of bilateral, rapidly progressing, necrotising scleritis in a post-surgical patient represents a case of bilateral surgically induced necrotising scleritis (SINS) complicated by secondary polymicrobial infection. SINS has been reported following bare sclera pterygium excision, though it is more commonly associated with adjunctive β irradiation, thiotepa, and mitomycin C.4–6 The time course of events, as well as the response to

Figure 1 (A) Right eye demonstrating a local area of scleral necrosis at the nasal limbus and a hypopyon. (B) Left eye demonstrating scleral necrosis with thinning, perforation, and iris prolapse at the nasal limbus.

Figure 2 Axial (A) and coronal (C) MRI images before proton beam therapy. The haemangiopericytoma is evident in the left medial orbit. (B) and (D) show the same views 7 years after conservative surgery and proton beam therapy.
immune suppression supports a primary autoimmune aetiology complicated, secondly, by a polymicrobial infection. Immune suppression, however, was initiated only after aggressive antimicrobial therapy.

The necrotising nature of the scleritis in our patient is consistent with the series by O’Donoghue et al in which a fourfold greater rate of necrosis occurred in post-surgical patients compared to a non-surgically induced scleritis population.2 In their series, the majority of patients (75%) had two or more surgical procedures before the onset of scleritis, and systemic immune suppression was necessary in 93% of patients. Our case similarly illustrates the need to consider immunosuppressive therapy in patients with postoperative necrosis.
