Actions of bevacizumab and ranibizumab on microvascular retinal endothelial cells: similarities and differences

Heidrun L Deissler,1 Helmut Deissler,2 Gabriele E Lang1

ABSTRACT

Background Retinal endothelial cells are crucially involved in the genesis of diabetic retinopathy which is treated with vascular endothelial growth factor (VEGF) inhibitors. Of these, ranibizumab can completely restore VEGF-induced effects on immortalised bovine retinal endothelial cells (iBREC). In most experiments supporting diabetic retinopathy therapy with bevacizumab, only non-retinal EC or retinal pigment epithelial cells have been used. Also, bevacizumab but not ranibizumab can accumulate in retinal pigment epithelial cells.

Objective To investigate the effects of bevacizumab on VEGF-induced changes of iBREC properties and potential uptake and accumulation of both inhibitors.

Methods Uptake of VEGF inhibitors by iBREC with or without pretreatment with VEGF165 was visualised by immunofluorescence staining and western blot analyses. Measured transendothelial resistance (TER) of iBREC (±VEGF165) showed effects on permeability, indicated also by the western blot-determined tight junction protein claudin-1. The influence of bevacizumab on proliferation and migration of iBREC was studied in the presence and absence of VEGF165.

Results Bevacizumab strongly inhibited VEGF-stimulated and basal migration, but was less efficient than ranibizumab in inhibiting VEGF-induced proliferation or restoring the VEGF-induced decrease of TER and claudin-1. This ability was completely lost after storage of bevacizumab for 4 weeks at 4°C. Ranibizumab and bevacizumab were detectable in whole cell extracts after treatment for at least 1 h; bevacizumab accumulated during prolonged treatment. Ranibizumab was found in the membrane/organelle fraction, whereas bevacizumab was associated with the cytoskeleton.

Conclusion Both inhibitors had similar effects on retinal endothelial cells; however, some differences were recognised. Although barrier properties were not affected by internalised bevacizumab in vitro, potential adverse effects due to accumulation after repetitive intravitreal injections remain to be investigated.

INTRODUCTION

Vascular endothelial growth factor (VEGF) and its receptors are promising targets for treating diabetic retinopathy (DR), particularly diabetic macular oedema (DME), as elevated levels of VEGF have been found in the vitreous fluid and retinal vasculature of patients.1–3 Accordingly, the VEGF-binding antibody fragment ranibizumab has recently been approved for DME therapy; the humanised VEGF-specific antibody bevacizumab is also used.4 5 The most important variant, VEGF165, not only elevates permeability of retinal endothelial cells (REC), likely leading to DME in vivo, but also stimulates proliferation and migration of REC to initiate neovascularisation,6–12 Several in vitro studies have confirmed that VEGF-stimulated proliferation of retinal or choroidal endothelial cells is inhibited by ranibizumab or bevacizumab.10 12 13 Increased permeability of immortalised bovine REC (iBREC) induced by long-term exposure to VEGF165, accompanied by loss of plasma membrane-localised tight junction (TJ) protein claudin-1, was completely restored by treatment with ranibizumab, even in the presence of other growth factors.9 14 Despite their similarity, deviating pharmacological activities of the VEGF inhibitors may result from differences in accumulation in relevant cell types, which has been shown for retinal pigment epithelial (RPE) cells: only bevacizumab was transported through the plasma membrane and its intracellular amounts increased over several days.15 Sufficiently accumulated bevacizumab affected phagocytic uptake of photoreceptor outer segments by RPE cells and also their barrier function.15 16 In contrast, ranibizumab only transiently impaired the barrier formed by these cells, and their phagocytotic uptake was not altered by exposure to this drug.16 17 These findings suggest that mechanisms of therapeutic activity of both VEGF inhibitors involving REC might also differ in relevant details. Therefore we used the established model cell line iBREC to investigate the efficiency of bevacizumab to restore VEGF-induced effects on proliferation, migration and barrier function. In addition, uptake of both VEGF inhibitors by iBREC and potential consequences were studied.

MATERIALS AND METHODS

Reagents, antibodies and media

Recombinant human VEGF165 was obtained from R&D Systems (Wiesbaden, Germany). Ranibizumab (Lucentis, 10 mg/ml), the Fab fragment of a humanised VEGF-binding antibody, was a gift from Novartis Pharma (Nuremberg, Germany).18 The anti-VEGF antibody bevacizumab (Avastin, 25 mg/ml) was purchased from Roche Pharma (Basel, Switzerland); aliquot parts were stored in inert plastic vessels at 4°C.19 Alternatively, bevacizumab was repackaged at the pharmacy of the University Hospital Ulm and provided in syringes which were stored at 4°C. Rabbit polyclonal antibodies binding to human claudin-1 (JAY8) or claudin-5 (Z43.JK) and AlexaFluor 594-conjugated detection antibodies were from Invitrogen (Karlsruhe, Germany); goat polyclonal antibodies directed against canine VEGF (cross-reacting with bovine VEGF) were from R&D Systems.
Cultivation of iBREC and treatment with growth factors and inhibitors
Telomerase-immortalised microvascular endothelial cells from bovine retina (iBREC) were cultivated in endothelial cell growth medium (ECCM: Promocell, Heidelberg, Germany) supplemented with 0.4% endothelial cells growth supplement/H, 10 ng/ml epidermal growth factor and 105 nM hydrocortisone and 5% fetal calf serum (FCS) as described previously.14 20

Prior to experiments with confluent iBREC, the serum concentration of ECCM was reduced to 0.25% FCS for 24 h. After treatment with 100 ng/ml VEGF165 for 2 days, cells were incubated with medium containing 100 ng/ml VEGF165, and 100 µg/ml ranibizumab or 250 µg/ml bevacizumab, for at least 24 h before cell extracts were prepared.14 To study the effect of VEGF inhibitors on unstimulated cells, iBREC were kept in medium with 100 µg/ml ranibizumab or 250 µg/ml bevacizumab for periods from 30 min to 6 days.

Preparation of subcellular fractions and western blot analyses
Subcellular fractions were prepared with the ProteoExtract Subcellular Proteome Extraction Kit (Merck, Darmstadt, Germany) according to the manufacturer’s instructions, yielding proteins localised in the cytosol, in membranes/organelles, in the nucleus, and in components of the cytoskeleton. Cytosolic, membrane and nuclear fractions were cleared by additional centrifugation (10 000 × g, 4°C) for 10 min.

Western blot analyses of whole cell extracts or subcellular fractions were performed as described.11 14 Analyses of ranibizumab and bevacizumab were based on immunoreactivity of polyclonal antibodies (coupled to horseradish peroxidase) with human IgG (1:20000, Invitrogen). For semi-quantitative assessment, specific chemiluminescence signals were compared to those of standard samples used in the range 0.5—50 ng.

Immunofluorescence staining
Confluent monolayers of iBREC on fibronectin-coated two-chamber slides (Nunc, Wiesbaden, Germany) were treated with effectors as described above and antigens were visualised by immunofluorescence staining.10 Internalised ranibizumab or bevacizumab were stained by incubation with AlexaFluor594-coupled polyclonal antibodies (1:10000) against human IgG for 90 min after blocking with 10% FCS/PBS for 30 min. To determine the limit of detection, diluted samples of the inhibitors were spotted on an appropriate membrane and processed alike.

Transendothelial electrical resistance of cell layers
To assess paracellular permeability of iBREC, transendothelial electrical resistance (TER) was measured as described previously.11 14 Normalised TER values were calculated in relation to the TER measured in low serum medium immediately before the medium was replaced by fresh medium containing effectors.

Cell migration and proliferation assays
Cell migration assays were performed in a modified Boyden chamber; enzymatic conversion of WST-1 (Roche), indicative of cell proliferation and migration of iBREC with VEGF165 is completely suppressed by 100 µg/ml ranibizumab.10 To compare the inhibitory effect of the related drug bevacizumab, serum-starved iBREC were exposed to VEGF165 and bevacizumab for 24 h before conversion of WST-1 was determined as a measure of cell proliferation. Only partial inhibition of VEGF-stimulated proliferation by bevacizumab was observed under these conditions (figure 1A). VEGF-stimulated migration of iBREC towards fibronectin in a modified Boyden chamber was not only strongly inhibited by bevacizumab, but was even driven below basal migration rates (figure 1B). The effect of bevacizumab on proliferation or migration of iBREC was not dependent on time and conditions of its storage prior to the experiments.

Bevacizumab restores a VEGF165-impaired iBREC barrier
In accordance with previous investigations, treatment of iBREC with VEGF165 significantly decreased the TER within 2 days (figure 2A).14 After addition of bevacizumab to the VEGF-pretreated cells, TER increased within 1 day but reached normal values only during prolonged exposure (figure 2A), whereas almost complete reversion was achieved after 1 day with ranibizumab. Like ranibizumab, bevacizumab completely reinstated the VEGF-induced loss of claudin-1 (figure 2B,C). This effect of potential therapeutic relevance on TJs was entirely lost after...
storage of the repackaged solutions of bevacizumab at 4°C for more than 4 weeks (figure 2B). In contrast, ranibizumab effectively reverted the loss of claudin-1 when stored under the same conditions (figure 2C). Whereas the capacity of bevacizumab to revert VEGF-induced vanishing of claudin-1 was dependent on its storage history, prevention of this process was not affected, even after prolonged storage (figure 2D). Western blot analyses confirmed that neither protein fragmentation nor formation of aggregates occurred during long-term storage of bevacizumab or ranibizumab solutions.

Uptake of bevacizumab and ranibizumab by iBREC

First we confirmed that the Fab fragment ranibizumab and the whole antibody bevacizumab were both bound by polyclonal antibodies against human IgG, and that the detection limits (25 ng for immunofluorescence staining, 0.5 ng for western blot analyses) were low enough. To monitor uptake by iBREC, their confluent monolayers were incubated with bevacizumab or ranibizumab for various periods from several hours to 6 days. Internalised drugs were visualised by immunofluorescence staining or determined in cell lysates (figures 3 and 4). After treatment for 30 min, a diffuse bevacizumab-specific staining was observed, which was focused around the nucleus in cells that had been exposed longer to this antibody (figure 3, right column). Staining intensity and pattern were not affected by pretreatment with VEGF165 for 1 day. In contrast to the observed uptake of bevacizumab, considerable amounts of ranibizumab were not detected by immunofluorescence staining in iBREC treated with this antibody fragment (figure 3, middle column). These results were confirmed by western blot analyses of whole cell extracts of iBREC treated with the VEGF inhibitors: bevacizumab was detectable after 1 h and accumulated during further incubation until day 6 (figure 4A). In contrast, less ranibizumab was taken up slower by iBREC and, despite prolonged incubation with the antibody fragment, the amount of internalised ranibizumab remained constant (figure 4B). Most of the bevacizumab absorbed by iBREC was found associated with the cytoskeleton and a smaller part in the subcellular fraction consisting of membranes and organelles (figure 4C), whereas ranibizumab was present in the membrane/organelle fraction but did not co-occur with cytoskeleton proteins (figure 4D). The different subcellular localisations of ranibizumab and bevacizumab were not affected by extended exposure or pretreatment with VEGF165. In these experiments, VEGF was mainly detected in the membrane/organelle fraction in the absence or presence of VEGF inhibitors.

Effects of bevacizumab and ranibizumab on barrier, migration and proliferation of unstimulated iBREC

Destabilisation of the cell barrier, as reported for bevacizumab-treated RPE cells, was not observed when TER of iBREC was monitored during incubation with ranibizumab or bevacizumab for up to 6 days (figure 5A). Constant localisation of the tight-junction proteins claudin-1 and claudin-5 in the plasma...
membrane was also indicative of a strong and stable barrier (Figure 5B,C).

Migration of iBREC towards fibronectin was not altered in the presence of 60 μg/ml ranibizumab as shown by normalised migration rates of 104%±34% versus 100%±31% (control). In contrast, 150 μg/ml bevacizumab strongly and significantly reduced basal migration rates of iBREC (normalised values of 43%±27%, p<0.0001 for comparisons with control and ranibizumab-treated cells), indicating VEGF-independent effects of bevacizumab. Basal proliferation of iBREC (normalised rates of 100%±12%) was not significantly affected by ranibizumab (104%±12%) or bevacizumab (94%±18%).

**DISCUSSION**

The humanised VEGF-binding antibody bevacizumab is widely used off-label to treat DME. Although REC are considered the most important target cells of VEGF in the development and progression of this disease, in vitro experiments performed to understand the mechanisms of the therapeutic effects of bevacizumab have been focused almost exclusively on non-retinal EC or RPE cells. In this investigation we used iBREC, a retinal cell line with the distinct advantage over primary ECs that contaminating cells of other types cannot be present in the cultures. Studies with iBREC ideally complement investigations based on rodent models of diabetes and may even be more relevant to clinical applications of drugs under investigation, because of the higher similarity of bovine proteins to their human counterparts. In our previous studies based on the iBREC model, we showed that ranibizumab, in addition to efficient inhibition of VEGF-stimulated proliferation and migration, can completely restore the VEGF-induced impairment of the endothelial barrier; this provided a rationale for using this antibody fragment in DME therapy. Stimulation of iBREC was carried out in these experiments, with concentrations of VEGF similar to those measured in the vitreous fluid of DR patients; concentrations of ranibizumab and bevacizumab reflected values found to be achievable by standard therapies with these drugs. We confirmed that bevacizumab inhibits VEGF-induced proliferation but is less efficient than ranibizumab; this was also observed in experiments with human REC and could be a consequence of its much lower affinity to VEGF. Likewise, the ability of bevacizumab to re-establish an intact iBREC barrier that had been deranged by VEGF was lower than that of ranibizumab. Despite being observed in vitro, this difference might be seen as a challenge to the assumption that both drugs are equivalent in the treatment of DR. Also of potential relevance for its clinical application is the surprising finding that bevacizumab repackaged in syringes and stored at 4°C for more

Figure 5 Transendothelial resistance (TER) and localisation of claudin-1 were not altered by bevacizumab or ranibizumab. Confluent immortalised bovine retinal endothelial cells (iBREC) were treated with bevacizumab or ranibizumab for several days. (A) Constantly high TER, indicative of a stable iBREC barrier, was measured despite the presence of vascular endothelial growth factor (VEGF) inhibitors during cultivation. (B) Unchanged expression of claudin-1 and claudin-5 by iBREC treated for 6 days with VEGF inhibitors was determined by immunofluorescence staining. (C) Western blot analyses of subcellular fractions of iBREC treated with VEGF inhibitors for 1 day showed stable expression and localisations of claudin-1 and claudin-5.

than 2 weeks lost its ability to restore VEGF-induced loss of claudin-1, an indicator of an intact barrier. In one previous study, loss of bevacizumab activity was reported to be caused by freezing and thawing, after which it failed to prevent VEGF-stimulated increase of permeability of choroidal EC.\textsuperscript{21} It has been suggested that partial inactivation of bevacizumab in solution might be due to formation of antibody aggregates with potentially masked binding sites, a process more frequently observed when the solutions were stored in syringes.\textsuperscript{22}\textsuperscript{23} However, in solutions of bevacizumab used in this study, such aggregates were undetectable; we assume that partial loss of activity was more likely caused by yet unidentified reactions leading to modification of the protein. In contrast to the rever-}
effect not observed with ranibizumab.\textsuperscript{16} Considering the typical ages of the DME-patients and duration of treatment, these results strongly suggest further investigations to exclude any harmful long-term consequences for retinal cells due to accumulation of bevacizumab after repetitive injections.
