Effect of diabetes associated increases in lens optical density on colour discrimination in insulin dependent diabetes

Kevin J Hardy, John H B Scarpello, David H Foster, Jack D Moreland

Abstract

Optical density (OD) of the crystalline lens has been shown in non-diabetics to increase linearly with age over the first five decades and at an increased rate thereafter; in insulin dependent diabetic (IDDM) patients, lens OD increases with age and with duration of diabetes at a rate similar to that in non-diabetics over the age of 60 years. Recently, it has been established that colour discrimination is abnormal in a majority of young patients with uncomplicated IDDM and angiographically normal retinas. Colour discrimination loss was attributed to functional abnormalities in the retina or neural pathways; yet the possibility exists that increases in lens OD may account for part or all of the colour discrimination loss in IDDM. In the present study, colour discrimination was compared in aretinopathic IDDM patients and age-matched controls, and then in a group of aretinopathic IDDM patients individually matched to controls with respect to lens OD. Colour discrimination was significantly worse in diabetic patients than in age-matched controls, and was significantly worse when diabetic patients were compared with controls matched for OD. The magnitude of the difference in 100 hue error score between diabetic patients and OD matched controls was, however, considerably less than the difference between diabetic patients and age-matched controls. These data suggest that colour discrimination loss in aretinopathic IDDM patients cannot be explained solely on the basis of diabetes induced increases in lens OD, but must involve abnormalities of the retina or its neural connections.

(*Br J Ophthalmol* 1994; 78: 754-756)

counterparts, and that increases in OD are strongly correlated with diabetes duration.⁶ Using psychophysical techniques, Lutze and Bresnick⁷ confirmed accelerated lens yellowing in young insulin-dependent diabetic (IDDM) patients and showed that lens yellowing increased with age and with duration of diabetes at a rate similar to that in non-diabetics older than 60 years. Recently, it has been shown that colour discrimination is abnormal in a majority of young patients with uncomplicated IDDM without retinopathy⁸; it was assumed that these changes in colour discrimination represent functional disturbances in the retina or post-retinal neural pathways; yet the possibility exists that changes in lens OD may explain all or part of this colour discrimination loss. The aim of the present study was to assess the contribution of premature increases in lens OD to colour discrimination loss in young uncomplicated type 1 diabetic patients without retinopathy.

Methods

SUBJECTS

Thirty eight young patients with uncomplicated IDDM of mean age 26.1 (SD 6.8) years and with mean diabetes duration of 8.1 (4.9) years were investigated and compared with 36 age-matched controls. Patients had stable intermediate term blood glucose control with a mean glycated haemoglobin of 10.2% (1.9%) (Corning method, laboratory reference range 5.5-8.2%). Eye examination in the diabetic patients comprised corrected Snellen acuity, tonometry, slit-lamp examination of the lens and anterior chamber, fundus photography, and fluorescein angiography, all of which were normal in every patient. Twenty five of the diabetic patients were then individually matched to non-diabetic controls on the basis of lens OD (appropriate controls could not be found for the other 13 patients). None of the controls were receiving medication, none had a history of diabetes or eye disease, and none was known to have abnormal colour vision. Controls did not have earlier experience of the 100 hue test. The study was approved by the North Staffordshire Hospital ethics committee and all subjects gave written informed consent before study.

MATCHING CONTROLS FOR OPTICAL DENSITY

Controls of equal OD were matched according to age by means of the following calculations.

From the Pokorny *et al*³ model of lens aging,

Optical density (OD) of the crystalline lens increases with increasing age and with decreasing wavelength of light.^{1,2} The increased absorption of short wavelength light sometimes causes the lens to appear yellow. Analysis of combined data from psychophysical and physical measurements of lens absorption has shown that in the general population lens OD increases at a constant rate with age until approximately 60 years of age and at a greater rate thereafter.³ In diabetes, however, fluorophotometry,⁴ quasi-elastic light scattering spectroscopy,⁵ Scheimflug photography,⁶ and psychophysical measurements⁷ have all demonstrated an increased rate of lens yellowing. Using Scheimflug photography, Sparrow *et al*⁶ demonstrated that even patients with relatively short diabetes duration have lenses of greater OD than their non-diabetic

the lens optical density D is given in terms of age A (in years) by

$$D = D_1[p + q(A-r)] + D_2$$

where D_1 , D_2 are wavelength dependent constants, and p , q , and r are age range constants. For the Lutze and Bresnick experiment,⁷ D_1 , D_2 represent OD differences at wavelengths 420 and 550 nm respectively. Thus

$$D_1 = 0.340$$

and

$$D_2 = 0.300$$

(see Pokorny *et al*³). From the Pokorny *et al* constants for young (Y) and old (O) eyes, the corresponding lens ODs are

$$D_Y = 0.4224 + 0.0068A \quad (1)$$

and

$$D_O = -0.5303 + 0.02268A \quad (2)$$

From equation (1), the predicted age is

$$A = (D_Y - 0.4224)/0.0068 \quad (3)$$

For a young diabetic patient, the lens OD B is given in terms of diabetes duration T (in years) by

$$B = D_Y + 0.017T \quad (4)$$

where the regression line in Figure 3a of the Lutze and Bresnick study⁷ has been constrained to pass through the origin. This differs from the unconstrained expression ($B = D_Y + 0.0173T - 0.0260$) used by Moreland,⁹ but the effect on the age of the lens equivalent controls is small.

From equations (1)–(4), the lens equivalent normal age E is given by

$$E = [(0.4224 + 0.0068A + 0.017T) - 0.4224]/0.0068$$

which, after simplification, becomes

$$E = A + 2.5T \quad (5)$$

Equation (5) is valid for values of E between 20 and 60 years.

If $E > 60$ years, then a similar analysis shows that

$$E = 42.0 + 0.30A + 0.75T \quad (6)$$

With the aid of equations (5) and (6), 25 diabetic patients were matched individually to controls whose ages were such that they had equal lens ODs. The acceptable precision of age differences between control and diabetic patients was estimated from a polynomial fit of the data of Verriest *et al*¹⁰ in which square root 100 hue error scores were expressed as a function of age. Table 1 shows interpolated values from the polynomial fit, and it can be seen that, for the age range of interest (23–69 years), the most sensitive age-dependent region is around 35 years. Here a 1 year age change produces the same percentage change in square root 100 hue error score, namely 2.4%, as a 5 year age change at age 50 years. This critical interval of plus or minus 2.4% in the square root 100 hue error score was used to define the acceptable precision of the difference. Table 2 shows the ages of the 25 diabetic patients and their OD matched controls.

Table 1 Interpolation table from 7th order weighted polynomial fit (99.996% fit) of the data of Verriest *et al*¹⁰ on the relation between colour discrimination and age

COLOUR DISCRIMINATION ASSESSMENT

Colour discrimination was assessed with the Farnsworth-Munsell 100 hue test (Kollmorgen Corporation, Baltimore, MD, USA) as described previously.⁸ Briefly, each subject performed the 100 hue test monocularly under a simulated North Sky light (Northlight, Thorn EMI Lighting, London, UK) according to the original instructions.¹¹ The original Farnsworth scoring convention was also used.¹¹ Meter read capillary blood glucose measurements (ExacTech System, Baxter Travenol Laboratories Inc, IL, USA) estimated at –1 hour, –30 minutes, and immediately before and after the 100 hue test were stable in all patients (mean peri-test blood glucose 9.7 (3.8) mmol l⁻¹ (range 5–20 mmol l⁻¹)). No patient was hypoglycaemic during colour vision assessment.

STATISTICAL METHODS

All data are expressed as mean (1 SD) unless otherwise stated. 100 Hue error scores are abnormally distributed and were therefore normal-

ised by a square root operation according to the method of Kinnear.¹² Comparison of 100 hue error scores in diabetic patients and age-matched controls was by an unpaired two tailed Student's *t* test. Comparison of 100 hue error scores in diabetic patients and individually OD matched controls was by Student's *t* test for paired comparisons.

Results

Colour discrimination performance in the diabetic group, age-matched controls, and controls matched for lens OD are shown in Table 3. There was a highly significant difference in colour discrimination ability between diabetic patients and age-matched controls (mean (SE) square root 100 hue error score for diabetic patients 9.0 (0.3) versus 4.9 (0.3) in age-matched controls, $p<0.001$). However, there was also a significant difference in colour discrimination ability between diabetic patients and controls matched for lens OD (mean (SE) square root 100 hue error score for diabetic patients 9.1 (0.6) versus 6.7 (0.4) for lens OD matched controls, $p<0.005$). Visual inspection and Fourier analysis¹³ of a polar plot of each patient's 100 hue test result showed no evidence of a specific axis of colour discrimination impairment.

Discussion

The results of this study suggest that colour discrimination loss in young IDDM patients without retinopathy is the result of changes both in the crystalline lens and in the retina or its neural connections. Despite stable short and intermediate term diabetes control, colour discrimination was highly significantly worse in diabetic patients than in age-matched non-diabetic controls, and was also significantly worse in diabetic patients than in controls matched for lens OD. If increases in lens OD were the sole cause of colour discrimination loss in diabetic patients, matching for OD would have compensated for the loss, but a significant difference between the two groups persisted. Increases in lens OD preferentially affect transmission of short wavelength light (lens yellowing); the lack of a specific axis of colour discrimination impairment in this study suggests a relatively small contribution of increases in lens OD to colour discrimination impairment.

It may be relevant that the magnitude of the difference between the mean square root 100 hue error scores for diabetic patients and OD matched controls (9.1 versus 6.7) was considerably less than the difference between diabetic patients and age-matched controls (9.0 versus 4.9). Expressed another way, there was a

significant difference in colour discrimination ability between the two kinds of control groups (mean square root 100 hue error score for age-matched controls was 4.9 (1.8) versus 6.7 (2.2) for OD matched controls, $p<0.001$). The OD matched controls, however, were selected on the basis of age-induced changes in lens OD, and were significantly older than age-matched controls (44 (12) years OD matched controls versus 25 (4) years age-matched controls, $p<0.001$). Colour discrimination ability is known to deteriorate with age, although the extent to which this deterioration results from age-related increases in lens OD rather than from reduced cone pathway sensitivity is unclear. Ruddock suggested¹⁴ that response of the receptor system of the eye remains largely unchanged with age. But, as Weale has pointed out,¹⁵ the sample on which Ruddock based these observations was small, and Ruddock himself was somewhat guarded in his conclusions about preservation of receptor function with age. In contrast, spectral sensitivity measurements by Werner and Steele¹⁶ suggest that all three cone types, or at least one of their post-receptor pathways, or possibly both receptors and post-receptor pathways, deteriorate with age.

In summary, the present findings suggest that colour discrimination loss in aretinopathic IDDM patients cannot be explained solely on the basis of diabetes induced increases in lens OD, but must involve abnormalities of the retina or its neural connections or both. The precise extent to which diabetes induced premature increases in lens OD contribute to colour discrimination loss in IDDM remains to be determined.
