Agreement in assessing optic discs with a digital stereoscopic optic disc camera (Discam) and Heidelberg retina tomograph

Velota C T Sung, Anna Bhan, Stephen A Vernon

Br J Ophthalmol 2002;86:196-202

Aims: To assess the intraobserver agreement, interobserver agreement, and the agreement between a digital stereo optic disc camera (Discam) and Heidelberg retina tomograph (HRT) in measuring area cup-disc ratio (ACDR) and radial cup-disc ratio (RCDR) by two observers.

Methods: The optic discs of 78 eyes of 39 people (17 cases of primary open angle glaucoma, eight normal tension glaucoma, two ocular hypertension, and 12 normal subjects) were imaged with Discam and HRT. Two observers independently drew the disc margins on the HRT mean topography images and the disc and cup margins on the Discam images. ACDR and the RCDR at various angles were measured with the two systems. Intraobserver agreement, interobserver agreement, and the agreement between the two systems were assessed by 95% tolerance limit of changes (TC) and intraclass correlation coefficient (ICC).

Results: Eight eyes were excluded due to poor image quality (six Discam and two HRT). 70 eyes were analysed. The intraobserver ACDR agreement was almost perfect in both systems (ICCs = 0.97 and 0.92, and TCs = 11.0% and 15.1% in HRT and Discam respectively). The interobserver ACDR agreement was almost perfect in HRT (ICC = 0.97) and substantial in Discam (ICC = 0.79), (TCs = 10.5% and 24.5% respectively). The ACDR agreement between the two systems was substantial in observer A (ICC = 0.67) and moderate in observer B (ICC = 0.53), (TCs = 24.8% and 46.7% respectively). The HRT measured the ACDR significantly larger than the Discam ($p < 0.001$), and the differences were significantly larger in the glaucomatous group ($p < 0.001$). RCDR agreement between the two systems was fair to substantial in observer A (ICC = 0.36 to 0.74) and slight to moderate in observer B (ICC = 0.12 to 0.45). Both observers achieved the best RCDR agreement between the two systems at the inferior optic disc position.

Conclusion: There is almost perfect intraobserver agreement in each system. The interobserver agreement was better with the HRT than the Discam. There was substantial variation in ACDR and RCDR agreement between the two systems measured by the two observers. The variation in ACDR and RCDR measurements between the two systems may be too large for interchangeable use in a clinical setting.

Optic disc assessment is important for early detection, monitoring, and management of glaucoma patients. Clinical evaluation of optic disc parameters with direct or indirect ophthalmoscopy has been shown to be poor among glaucoma specialists.^{1,2} The use of stereoscopic optic disc photography to assess optic discs has been shown to reduce the variability in assessing the vertical and horizontal cup-disc ratios.^{3,4} However, intraobserver agreement has been shown to be better than the interobserver agreement, and the interobserver agreement improves with observer experience.⁵ Recently, a digital optic disc stereoscopic camera known as Discam (Marcher Enterprises Ltd, Hereford, UK) has become available. This device allows rapid acquisition and storage of a pair of monochromatic stereoscopic optic disc images. The observer draws the disc and cup margins on the monitor for the computer to compute various cup-disc ratio parameters. Shuttleworth *et al* recently reported good intraobserver and interobserver agreement with this device.⁶

The development of the scanning laser ophthalmoscope in the late 1980s has provided a more objective and repeatable way of assessing optic disc parameters. Previous studies have shown high reproducibility with this device.^{7,8} Agreement between cup-disc ratios measured by stereoscopic optic disc photography and Heidelberg retina tomograph has been investigated in the past.^{9,10} However, as far as we know, there has been no report on the agreement in cup-disc ratio parameters between the scanning laser tomography and the digital

stereoscopic optic disc camera. In this study we assessed intraobserver agreement, interobserver agreement in each system and agreement between the two systems.

METHODS

Seventy eight eyes of 27 patients from the glaucoma clinic and 12 normal volunteer subjects were recruited in the study. Subjects in this study were recruited in accordance with the tenets of the Helsinki agreement. The research was approved by the ethics committee of Queen's Medical Centre, University Hospital NHS Trust. All patients from the glaucoma clinic had automated central 24 degrees visual fields plotted with Humphrey field analyser (Humphrey Instruments Inc, San Leandro, CA, USA) within 6 months of examination. Primary open angle glaucoma ($n=17$) was defined as (i) an intraocular pressure consistently above 21 mm Hg without antiglaucoma treatment, (ii) normal drainage angle and anterior chamber appearance with no apparent ocular abnormality that may account for the elevated IOPs, (iii) typical glaucomatous visual field defects and/or optic nerve head damage. Normal tension glaucoma ($n=8$) was defined as (I) an IOP never documented above 21 mm Hg, (ii) normal drainage angle and anterior chamber appearance, (iii) typical glaucomatous optic nerve head damage and visual field damage. Ocular hypertension ($n=2$) was defined as (i) an IOP above 21 mm Hg on two or more occasions, (ii) normal drainage angle and anterior

Figure 1 A screen capture picture of the Discam software showing a pair of stereoscopic optic disc images of an eye of a normal subject in the study. Observer A estimated the optic disc and cup margins.

chambers, (iii) normal optic discs and visual fields. All normal subjects ($n=12$) had full ophthalmological examinations and visual fields plotted by a Friedmann Mark I visual field analyser. All had a visual acuity of 6/9 or better, normal optic disc appearance and normal visual field tests. All subjects had a refractive error of within 5 dioptres from emmetropia.

The Discam (Marcher Enterprises Ltd, Hereford, UK)¹¹ is a digital stereoscopic optic disc camera. A built-in rapidly moving shutter inside the camera captures sequential images of the optic discs at a viewpoint of about 20 degrees at the optic disc. A pair of monochromatic disc images (512×512 pixels) of slight disparity is projected onto the monitor. The stereoscopic images are viewed with a stereoviewer (ScreenVu) by the clinicians and the cup and disc margins of the optic discs are then drawn with a computer mouse. Discam software version 3.0 was used to analyse the images. The vertical cup-disc ratio, horizontal cup-disc ratio, perimeter cup-disc ratio and area cup-disc ratio are automatically calculated. Radial cup-disc ratios can be obtained by moving the pointer with the computer mouse to the point of interest near the disc margin. A radial marker, based upon the disc centre, will produce the radial cup disc ratio at that angle. Figure 1 shows a screen capture picture of the Discam software of an eye of a normal subject in the study.

The Heidelberg retinal tomograph (HRT, Heidelberg Engineering, Heidelberg, Germany)¹² is a confocal scanning laser ophthalmoscope utilising a diode laser source with a wavelength of 670 nm. Three dimensional retinal topography is generated from 32 consecutive and equidistant two dimensional optical image sections each consisting of 256×256 pixel elements. A field size of 15×15 degrees was used for image capture, and software version 2.01 was used to analyse the topography images. The standard reference plane is defined as $50 \mu\text{m}$ posterior to the mean retinal surface of a segment of 6 degrees starting from 4 degrees below the temporal-horizontal position of the disc margin, which is defined by the contour line drawn by the clinician. The area cup-disc ratio is computed from the stereometric analysis of segment 0–360 degrees by the HRT software. Radial cup-disc ratios with the centre of the contour circle at the disc margin as centre can be computed by entering the degree of the angle of interest as the segment limit of the stereometric analysis of the HRT software.

Both eyes of each subject were imaged by both systems, by one examiner (VCTS), on the same day. Pupils were dilated by one drop of 1% tropicamide. At least three HRT images and Discam images were taken from each eye. The mean HRT topography was computed from three topography images with the HRT software. A good quality Discam image was chosen for each optic disc. Two ophthalmology trainees were defined as observer A and B (VCTS and AB respectively), both with at least 5 years of clinical experience in ophthalmology. They have similar stereopsis, both measured to be 30 second of arc by TNO random dot test (Lameris Ootech BV, Netherlands). Each observer independently drew the optic disc margins on the HRT mean topography images and the cup and disc margin of the chosen Discam optic disc images while being masked from the diagnosis and each other's drawings. In addition, observer A redrew the HRT mean topography images and the Discam images of the same group of eyes 3 months later. The area cup-disc ratio (ACDR), the radial cup-disc ratio (RCDR) at superotemporal, inferotemporal, superior, temporal, inferior, and nasal positions of both HRT and Discam disc images were computed. Intraobserver agreement, interobserver agreement, and the agreement between the two systems in assessing these cup-disc ratio parameters were assessed by methods described by Bland and Altman.¹³ We also used intraclass correlation coefficient (ICC) to assess the level of agreement as described by Fleiss and Cohen.¹⁴ Table 1 shows the interpretation of the ICC as described by Landis and Koch.¹⁵ Shrout and Fleiss described six kinds of ICCs.¹⁶ The two way mixed effects model and single measure reliability of

Table 1 Interpretation of intraclass correlation coefficients (ICC)

ICC	Agreement
1.0	Perfect agreement
0.99 to 0.81	Almost perfect agreement
0.80 to 0.61	Substantial agreement
0.60 to 0.41	Moderate agreement
0.40 to 0.21	Fair agreement
0.20 to 0.01	Slight agreement
0.0 to -0.1	Poor agreement

HRT ACDR – Discam ACDR observer B	0.075 (0.16)	0.037 to 0.11	-0.25 to 0.40	46.67	0.53 (0.30 to 0.70)

the reliability analysis of spss for Windows version 9 (SPSS Inc, Chicago, IL, USA) was used in the study. The HRT and Discam (judges) were considered fixed effect, while the cup-disc ratios measured by these two systems (targets) were considered random effects. The 95% tolerance limit of change (TC) is 1.96 times the standard deviation of the difference between two measurements divided by the range of the average of the two measurements. This expresses the tolerance for change as a percentage of the range of the average of the two measurements. Paired *t* tests and unpaired *t* tests were used to test for significant differences between measurements, with a *p* value <0.05 considered significant.

RESULTS

Seventy eight eyes of 39 subjects were recruited to the study. Six eyes (7.7%) with poor Discam images were excluded from the study because of lenticular opacities or a poorly dilated pupil. Two eyes (2.6%) had poor mean HRT topography images because of excessive eye movement. A total of 70 eyes were successfully analysed, the patient demography and diagnoses are listed in Table 2.

Figure 2 Regression plot of difference in HRT ACDR against the average of HRT ACDR in two measurements for observer A ($R^2 = 0.002$, $p = 0.7$). **Figure 3** Regression plot of difference in Discam ACDR against the average of Discam ACDR in two measurements for observer A ($R^2 = 0.04$, $p = 0.08$).

Figure 4 Regression plot of difference in HRT ACDR against the average of HRT ACDR in two measurements from observer A and observer B ($R^2 = 0.03$, $p = 0.15$).

Figure 5 Regression plot of difference in Discam ACDR against the average of Discam ACDR in two measurements from observer A and observer B ($R^2 = 0.003$, $p = 0.64$).

regression lines of both graphs have insignificant slopes ($R^2 = 0.03$ and 0.003 in HRT and Discam respectively). Table 4 shows the intraobserver agreement and interobserver agreement in measuring the vertical cup-disc ratio, horizontal cup-disc ratio, and perimeter cup-disc ratio with the Discam.

Comparison of the agreement between the HRT and Discam in measuring the ACDR taken by observer A and observer B is shown in Table 3. The agreement between the HRT and Discam measurements was better with observer A than observer B. The ICCs showed substantial agreement in observer A and moderate agreement in observer B (0.67 and 0.53 in HRT and Discam respectively). However, the 95% tolerance for change was rather large, being 24.8% and 46.7% in observer A and observer B respectively. Figures 6 and 7 show the regression plots of the difference in ACDR measured by the HRT and Discam against the average of the two measurements from both observer A and B. The slopes of the regression line in both graphs are significant ($R^2 = 0.42$ and 0.36 in observer A and B respectively, $p < 0.0001$ in both observers). This indicates that the HRT consistently measures a larger ACDR than the Discam in discs with larger cup size and vice versa. The HRT measured the ACDR significantly larger than Discam by an average of

Figure 6 Regression plot of difference in ACDR measured by the HRT and Discam against the average ACDR in two measurements from observer A ($R^2 = 0.42$, $p < 0.0001$).

Figure 7 Regression plot of difference in ACDR measured by the HRT and Discam against the average ACDR in two measurements from observer B ($R^2 = 0.36$, $p < 0.0001$).

0.08 estimated by both observers ($p < 0.001$, paired t tests) (Table 5). Subgroup analysis of optic discs with glaucomatous appearance (POAG and NTG) and normal appearance (normal and OHT) showed that the glaucomatous group had significantly larger differences between the HRT and Discam when estimating ACDR by both observers ($p < 0.001$, unpaired t tests) (Table 6).

Table 7 compares the agreement in measuring the RCDRs at various radial positions with the HRT and Discam in both observers. The positions considered were superotemporal, inferotemporal, superior, temporal, inferior, and nasal positions of the optic discs. The ICCs ranged from the lowest at the temporal position (0.36 and 0.12 with observers A and B respectively) to the highest at the inferior position (0.74 and 0.45 with observers A and B respectively) in both observers.

DISCUSSION

Assessment of optic disc cupping is of paramount importance in glaucoma management. Previous studies have shown that optic disc damage commonly preceded visual field loss.^{17,18} Therefore, a reproducible method of assessing the optic disc

Table 4 The intraclass correlation coefficients (ICC) and their 95% confidence interval (CI) of within observer (observer A) and between observers (observer A – observer B) in measuring vertical cup-disc ratio, horizontal cup-disc ratio and perimeter cup-disc ratio by Discam

Inferior	0.74 (0.61 to 0.83)	0.45 (0.24 to 0.62)
Nasal	0.52 (0.32 to 0.67)	0.37 (0.15 to 0.55)

cupping is important in detecting early progression in glaucomatous optic nerve head damage. Lichter *et al* demonstrated intraobserver agreement and interobserver agreement in estimating cup-disc ratio was better with stereoscopic than monoscopic photographs.¹⁹ However the traditional way of obtaining stereoscopic optic disc photographs by using a stereoscopic fundus camera is cumbersome and time consuming. The modern digital camera technology permits a cheap and effective way of capturing, storing, and analysing digital stereoscopic optic disc images.

In this study, one observer achieved almost perfect intraobserver agreement in assessing the ACDRs with the Discam (ICC = 0.92). In addition, the interobserver agreement between the two observers was substantial (ICC = 0.79). Since the same Discam images were used in intraobserver and interobserver studies, variability in images taken from the same eyes has been eliminated. The results of this study confirmed a common observation that the variability in assessing various cup-disc ratio parameters is higher between observers than within observers themselves.^{3–5 20 21} On the other hand, the results of this study compare favourably with previous studies on traditional colour stereoscopic optic disc photographs. Varma *et al* studied the intraobserver and interobserver agreement among glaucoma experts in assessing optic discs in monoscopic and stereoscopic conditions. The median weighted kappa (K_w) for intraobserver agreement was 0.79 for both monoscopic and stereoscopic conditions. For interobserver agreement, the median weighted kappas were 0.57 and 0.67 in monoscopic and stereoscopic conditions respectively.⁴ Abrams *et al* studied the intraobserver and interobserver

agreement among ophthalmologists, optometrists and residents in assessing the vertical cup disc ratio in stereoscopic conditions. They demonstrated good intraobserver agreement in all three groups (K_w = 0.69 – 0.79), and the interobserver agreement was significantly higher for ophthalmologists (K_w = 0.68) than for optometrists, and residents (K_w = 0.56).⁵ A recent study by Harper *et al* showed similar results to the others.²¹ They studied five observers (three optometrists and two ophthalmologists) grading vertical and horizontal cup-disc ratios on stereoscopic optic disc photographs. They found the K_w ranged from 0.70 to 0.84 within observers and from 0.23 to 0.64 between observers. However, our results are less favourable when compared with a recent study reported by Shuttleworth *et al* on the intraobserver and interobserver agreement in assessing various cup-disc ratio parameters with the same system.⁶ They demonstrated almost perfect intraobserver and interobserver agreement when two observers measured the ACDR (ICCs of 0.96 and 0.92 respectively). This study showed exceptionally good agreement between observers when compared with other studies using a stereoscopic photograph technique. The observers in this study may have better standardisation of optic cup delineation. The mouse cursor used in the Discam to draw the disc and cup margins was not set in depth at the plane of interest, and this may induce error during drawing from parallax effect. Nevertheless, optic cup margin estimation in stereoscopic methods is still the main source of variability in optic disc assessment.

Scanning laser tomography provides a reproducible, automatic three dimensional measurement of the topography of

the optic discs.^{7-8,22} It allows an objective assessment of the optic cup margin by a predefined reference plane. Various studies have compared the HRT measurements with stereoscopic methods. Zangwill *et al* studied the agreement between clinician measurements and the scanning laser ophthalmoscope when measuring vertical and horizontal cup-disc ratios. They found agreement was moderate to substantial for vertical cup-disc ratios ($K_w = 0.57$ to 0.72) and fair to moderate for horizontal cup-disc ratios ($K_w = 0.21$ to 0.55) in three glaucoma experts.⁹ Hatch *et al* recently found that agreement between the planimetric method and HRT when measuring area cup-disc ratios was moderate to substantial in three observers (ICC = 0.57 to 0.65).¹⁰ These findings are comparable with the results of the present study, in which Discam and HRT ACDR agreement from two observers was moderate to substantial (ICC = 0.67 and 0.53 in observer A and B respectively). The previous two studies defined the reference plane to be at $320\ \mu\text{m}$ below the retinal plane. In this study, we used the standard reference plane, which was set at $50\ \mu\text{m}$ posterior to the mean retinal height of a temporal segment of 6 degrees starting from 4 degrees below the temporal-horizontal position of the contour line at the disc margin. When we performed the same analysis on the same set of data with the reference plane set at $320\ \mu\text{m}$ below the retinal plane, the agreement results were very similar to the results we have presented here.

In this study, we found a linear relation between the difference in ACDR measurements (HRT – Discam) and the average ACDRs measured by the two methods (Figs 6 and 7). This indicates that the HRT tends to overestimate or the Discam underestimates the ACDR in eyes with larger optic disc cup size. On average, the HRT overestimated the Discam ACDR by 0.08 in this study. This is comparable with the results reported by Hatch *et al*.¹⁰ They found that the HRT overestimated the ACDR by 0.07 to 0.11 when compared with the planimetry obtained by three clinicians. Subgroup analysis showed the differences in measuring ACDR were significantly larger in eyes with glaucomatous optic disc appearance (Table 6). This is in agreement with previous studies by Dichtl *et al* and Jonas *et al*. Both studies compared the neuroretinal rim area measurement between a planimetric method and the HRT, using the same reference plane setting as in this study. They found that the HRT significantly overestimated the neuroretinal rim area compared with the planimetric method, and the differences were significantly larger in glaucomatous optic discs.^{23,24} They gave an explanation that the relative proportion of the size of the retinal vessels increases as the neuroretinal rim area decreases with the HRT method because of the algorithm of the HRT, whereas the loss of neuroretinal rim as assessed on the photograph outweighs the diminution of the retinal vessel calibre in eyes with glaucoma. One possible explanation of the discrepancies we found between the glaucomatous and normal optic disc when measuring ACDR in this study is that the HRT tends to measure the vertical optic disc diameter as smaller than the planimetric method by a constant amount ($0.13\ \text{mm}$).²⁵ This is probably due to a difference in pinpointing the Elshnig's ring between the two methods rather than a real "magnification" effect. The demarcation of the disc margins on the HRT images are dependent on the shape of the cup, the Elshnig's ring on the reflectivity image of the HRT is attenuated as the retinal surface is sloping towards the cup. This attenuation is especially more pronounced in discs with larger ACDR because of the steeper slope of the retinal surface. Logically, therefore, the HRT should produce a larger ACDR than the photographic method when measuring the same optic disc. This difference is proportionally larger in eyes with larger optic cup size, such as eyes with glaucomatous optic disc cupping.

Zangwill *et al* have studied the agreement between glaucoma expert evaluations of stereoscopic photographs and the HRT when measuring horizontal and vertical cup disc

ratios.⁹ They found the difference was larger in normal subjects than in glaucoma patients. Apart from the effect of cup shape on the HRT reflectivity image as explained above, another reason for their findings is that the clinicians commonly measure the cup diameter at the centre of the cup, whereas the HRT measures the diameter of the cup as it passes through the vertical meridian of the disc. In glaucomatous eyes, a larger cup will have a wider area of the cup passing through the vertical meridian of the optic disc; therefore, the difference between the two methods of estimation will be less. This is why we did not compare the vertical and horizontal cup-disc ratios between the HRT and Discam because the HRT vertical and horizontal cup-disc ratios are obtained from the ratio of a straight line drawing through the centre of the discs as defined by the disc margin, whereas the Discam software calculates the vertical and horizontal cup-disc ratio from the widest part of the cup to the widest part of the disc on the vertical and horizontal axis respectively. Instead we compared the radial cup-disc ratios at various angles. Interestingly both observers showed better agreement between the HRT and Discam measurements at the inferior RCDR. This is likely to be due to the more abrupt edge of the optic cup and the lack of retinal blood vessels at the inferior position in most glaucomatous optic cups. The implication of this observation merits further study on their correlation with functional deficit—that is, visual field loss.

In this study, we demonstrated that both the HRT and Discam had almost perfect intraobserver agreement by one observer. The interobserver agreement was almost perfect with the HRT and substantial with the Discam. The agreement between the HRT and Discam when measuring ACDR was moderate to substantial by the two observers as measured by using the ICC, but the 95% tolerance of change are rather large at 24.8% and 46.7% by observers A and B respectively. This difference may not allow interchangeable use of the ACDR measured by the HRT with that measured by the Discam. This is also likely to be true when the ACDR measured by the HRT is compared with those measured by routine slit lamp biomicroscopic examination with 90 or 78 dioptre lenses. More training and standardisation in cup margin determination may improve the interobserver agreement in the Discam system. This study was limited by using only two observers. Further studies on the agreement between more observers with different experience in optic disc assessment will be useful to explore the value of more widespread use of this system. With the advent of telemedicine technology, the ease of acquiring and storing of digital optic disc images with this system may have some implication in the future communication between the optometrists and hospital ophthalmologists. This may facilitate shared care of some patients—for example, patients with ocular hypertension, between community optometrists and hospital ophthalmologists.
