Longitudinal changes in axial length in high myopia: a 4-year prospective study

Min Woo Lee,1,2 Seong-Eun Lee,1 Hyung-Bin Lim,1 Jung-Yeul Kim1

ABSTRACT

Aim To determine the longitudinal changes in the axial length (AL) in patients with high myopia without any other ophthalmic disease.

Methods Participants were divided into two groups: a high myopia group (60 eyes) without myopic degeneration, such as choriotereinal atrophy or posterior staphyloma, and a control group (60 eyes). Both groups were further divided into subgroups according to the AL: subgroup 1 (≥27.5 mm), subgroup 2 (26.0–27.5 mm), subgroup 3 (24.5–26.0 mm) and subgroup 4 (<24.5 mm). The ALs were measured five times at 1-year interval using an IOL master, and the AL was fitted with linear mixed models.

Results In the high myopia group, the AL showed a relatively constant increase at each visit, and they were significantly different with previous measurements at most visits, whereas the control group showed no significant change of AL. Subgroups 1, 2 and 3 showed significant changes in AL over time (0.064, 0.032 and 0.012 mm/y, respectively). In univariate analyses, age, best-corrected visual acuity, baseline AL and anterior chamber depth were significantly correlated with changes in the AL in the high myopia group. In multivariate analysis, only baseline AL remained significant (p<0.001).

Conclusions Myopic eyes, including moderately myopic eyes, showed a consistent increase in AL over 4 years, and eyes with a longer baseline AL showed a greater increase in AL than eyes with a shorter AL.

INTRODUCTION

Myopia is often regarded as a benign disorder because vision can be corrected with glasses or contact lens. However, it is an important public health problem in eastern and southeastern Asian countries, including Singapore, China, Taiwan, Japan and Korea, due to its increasing prevalence in the past 50–60 years.1,2,3 Especially high myopia, which is defined as a spherical equivalent (SE) ≤−6.0 dioptres (D), can cause various retinal disorders. Chorioretinal atrophy, choroidal neovascularisation and macular retinoschisis can occur as the structure of a highly myopic eye becomes thinner due to fewer cross-linkages.3 The Tajimi study in Japan found that myopic macular degeneration was the leading cause of unilateral and bilateral blindness.5 Additionally, pathological myopia was the most common cause of low vision and blindness in a Chinese population aged ≥40 years.6

These conformational changes are closely related to the axial length (AL) of highly myopic eyes; thus, observation of change in the AL is clinically important. Larsen et al6 reported that the growth of the AL of the eye was found to reach adult length by 13 years of age in 1852 eyes with refractive errors of ±5 D. However, in high myopia, many studies have reported that the AL continues to increase.7,8 Saka et al9 reported that the highly myopic eyes with a longer baseline AL showed a greater increase in AL, suggesting the possibility that more myopic eyes became more myopic with increasing age. In their study, there were patients with posterior staphyloma about 32.4% among high myopia. Although it is not clear whether these structural abnormalities affected the change of AL, they may be intervening factors for identifying the effect of the degree of AL on its changes.

Therefore, to identify the association of baseline AL with subsequent changes therein in detail, we evaluated the longitudinal changes in patients with high myopia without structural changes, such as chorioretinal atrophy or posterior staphyloma, by comparing their eyes with those of normal individuals.

METHODS

Patients This prospective, longitudinal, observational study was approved by the Institutional Review Board of Chungnam National University Hospital, Daejeon, Republic of Korea, and adhered to the tenets of the Declaration of Helsinki. Patients who visited our retina clinic were enrolled and examined between May 2011 and September 2018, and informed consent was obtained from all patients. The high myopia group consisted of eyes with an AL ≥26.0 mm, and the control group consisted of eyes with an SE between +3.0 and −6.0 D, and AL <26.0 mm. To observe the effect of the degree of AL on AL changes, high myopia and control groups were divided into subgroups: subgroup 1 (≥27.5 mm), subgroup 2 (26–27.5 mm), subgroup 3 (24.5–26.0 mm) and subgroup 4 (<24.5 mm), respectively. In all, 30 eyes were included in each subgroup, for a total of 60 eyes per group. All subjects underwent a complete ophthalmic examination, which included detailed ophthalmoscopic examinations, best-corrected visual acuity (BCVA), intraocular pressure (IOP) using non-contact tonometry, SE, and keratometry. Participants were followed every year for 4 years. Exclusion criteria were a BCVA <20/25, IOP ≥21 mm Hg, any opthalmic disease except high myopia, a history of intraocular surgery including cataract extraction and cataract surgery during follow-up period. We also excluded eyes with high myopia including...
conformational abnormalities, such as chorioretinal atrophy or posterior staphyloma, which could affect AL changes, to observe the association of baseline AL with longitudinal changes therein in more detail.

The IOL Master (V.5.02, Carl Zeiss, Jena, Germany) was used for measuring the AL, anterior chamber depth and radius of corneal curvature. The measurements made by the IOL Master were repeated five times at each examination by a skilled examiner, and the average value was used in the statistical analyses.

Statistical analyses
Ocular parameters in the high myopia and control groups were compared using an independent t-test. To compare the AL measurements among timepoints, a paired t-test was used. P values were adjusted using the Bonferroni correction. Linear mixed models were performed to identify the rate of AL change in each subgroup. The AL was fitted with linear mixed models with time, age, IOP, sex, keratometry, initial anterior chamber depth and radius of corneal curvature as fixed effects. A random intercept was included at the eye level. Univariate and multivariate generalised linear mixed models were used to determine the factors associated with AL changes over time in the high myopia group. Statistical analyses were performed using SPSS V.18.0 software (IBM Corp., Armonk, NY, USA).

RESULTS
Demographics and AL measurements at each visit
Of the 126 eyes, four eyes in the high myopia group and two eyes in the control group were excluded because they underwent cataract surgery during the follow-up period. Overall, 60 eyes of 60 participants in each group were enrolled. The mean age of the high myopia and control groups were 40.6±13.4 years (range, 20–58 years) and 42.4±13.4 years (range, 21–57 years), respectively; they were not significantly different (p=0.494) (table 1).

Sex, BCVA, IOP and anterior chamber depth were also not significantly different. The average SE, AL, keratometry and radius of corneal curvature of the high myopia and control groups were 42.31±2.03 versus 43.24±1.82 (p=0.015), and 7.99±0.40 versus 7.82±0.34 (p<0.001), respectively.

In the high myopia group, the AL showed a relatively constant and typically significant increase versus previous visit (table 2).

The control group did not show a significant AL changes at most visits. The high myopia and control groups did not show a significant difference in SE between first and last visits (−8.26±4.01 D vs −8.43±4.98 D, p=0.761; −1.73±2.06 D vs −1.41±2.59 D, p=0.881, respectively).

The rates of AL changes in each subgroup
The rates of AL change in the high myopia and control groups were 0.047 and 0.011 mm/years, respectively. Subgroup 1 (≥27.5 mm) and subgroup 2 (26.0–27.5 mm), which are the high myopia subgroups, showed a noticeable increase in the AL over time (figure 1). However, subgroup 3 (24.5–26.0 mm) and subgroup 4 (<24.5 mm) did not show significant changes over time when compared with the high myopia subgroups. The rate of AL change in subgroup 1 was 0.064 mm/yr, which was statistically significant (p<0.001) (table 3).

In this study, the AL was fitted with linear mixed models with time, age, IOP, sex, keratometry, initial anterior chamber depth and radius of corneal curvature as fixed effects. A random intercept was included at the eye level. Univariate and multivariate generalised linear mixed models were used to determine the factors associated with AL changes over time in the high myopia group. Statistical analyses were performed using SPSS V.18.0 software (IBM Corp., Armonk, NY, USA).

The rates of AL changes in subgroup 2 and 3 were 0.032 mm/y and 0.012 mm/y, respectively; they were also statistically significant (p<0.001 and p=0.025, respectively). The rate of change in subgroup 4 was 0.006 mm/y, which was non-significant (p=0.054).

Factors affecting AL changes in high myopia

Univariate analyses showed that age, BCVA, baseline AL and anterior chamber depth were significantly associated with AL changes (p=0.045, p=0.003, p<0.001 and p=0.006, respectively) (table 4).

DISCUSSION

Highly myopic eyes can occur many kinds of conformational changes over time. Choudhury et al7 reported that myopic degeneration such as tessellation, peripapillary atrophy, posterior staphylooma or lacquer cracks was more prevalent among older patients. Numa et al10 reported that the mean and variance of fundus curvature increased with age, suggesting that the shape of the staphylooma was steeper and less smooth in elderly subjects. Our previous study also found that highly myopic eyes had a significantly greater decrease in the peripapillary retinal nerve fibre layer, and the reduction rate was greater in older patients.11 Such changes can cause visual impairment in patients with high myopia, so clinicians should observe those things carefully. Additionally, these changes are known to be associated with AL in previous studies.9 10 12 Therefore, those myopic degenerations could be predicted to some extent by measuring the AL and changes therein.

Our study enrolled a high myopia group without signs of myopic degeneration, such as chorioretinal atrophy or posterior staphylooma, to measure AL more accurately and evaluate the association of baseline AL with subsequent changes therein in more detail. In patients with these signs of myopic degeneration, it can be difficult to accurately measure the AL because of fixation loss. Furthermore, Yang et al13 reported that posterior staphylooma could be an important factor in AL measurements because it reduces their accuracy even with good fixation. Additionally, other previous studies have reported a correlation of the AL with posterior staphylooma.8 10 By excluding these interfering factors, we could measure the AL and changes therein more accurately and reliably.

In the high myopia group, keratometry and radius of corneal curvature were significantly different from the control group. Previous studies reported that there appeared to be a definite tendency towards steeper corneas in shorter eyes and flatter corneas in longer eyes, which confirmed the emmetropising relationship between the AL and corneal curvature.14 15 Our study showed significantly lower keratometry in the high myopia group, which was similar to previous studies. Jonas et al16 reported that a longer radius of corneal curvature was positively associated with a longer AL in young and adult populations, which is consistent with our results. Additionally, the anterior chamber depth was deeper in the high myopia group, although it was not statistically significant. Chung et al17 reported that the anterior chamber depth increased with increasing AL in moderately myopic eyes; however, the anterior chamber depth showed no further increase with eyeball elongation in highly myopic eyes. Other previous studies reported that high axial elongation was associated with a thinning of the sclera and choroid posterior to the equator, whereas scleral thickness in the pars plana and limbal regions did not significantly differ between axially elongated eyes and eyes with a normal AL.18–20 It seemed that the anterior chamber depth increased with increasing AL within limits; however, high axial myopia was associated with changes located mostly posterior to the equator.

The high myopia group showed a significant increase in AL at most visit, whereas the control group showed smaller and non-significant changes at most visit; this was consistent with previous studies.7 10 12 Saka et al21 explained this elongation of the AL as increased depth of the vitreous chamber, which is consistent with the previous histological studies mentioned above.19 20

Ohsugi et al21 reported that change in the AL in the high myopia without complication group was 0.041±0.05 mm/y. In our study, the rate of change in AL in the high myopia group was 0.047 mm/y, which is consistent with the previous study. In subgroup analyses, subgroups 1, 2 and 3 showed a significant change in AL over time, which consisted of moderate to high myopia. Additionally, there were higher rates of change in the longer AL subgroups, especially subgroup 1 (0.064 mm/y). Such a change in AL over time, which consisted of moderate to high myopia, may cause many problems, including changes in the SE. Surgery for refractive correction, such as posterior intraocular lens implantation after clear lens extraction, phakic intraocular lens implantation or laser-assisted subepithelial keratomileusis, has been done widely in high myopia these days; many previous studies reported difficulty of accurate prediction of SE or change in refractive error after these types of surgeries in high myopia.22–24 The change in AL would add a bad influence on a refractive error over time. Further longitudinal studies for real impact of AL change to SE in high myopia are needed.

Previous studies have reported a relationship between age and AL in normal eyes. Fotedar et al25 reported a decrease in the mean AL with increasing age: 23.61 mm (95% CI, 23.50 to 23.73 mm) in 59-year to 64-year-olds and decreased to 23.15 mm (95% CI, 22.83 to 23.47 mm) in ≥85-year-olds. Values in bold face (p<0.05) are statistically significant. In multivariate analyses, only baseline AL showed a significant association (p=0.001). ACD, anterior chamber depth; AL, axial length; BCVA, best-corrected visual acuity; IOP, intraocular pressure; RCC, radius of corneal curvature; SE, spherical equivalent.
also reported that with increasing age, the mean AL decreased ($r=-0.127; p<0.001$). Subgroup 4 (AL<24.5 mm) in our study showed a 0.006 mm/year rate of increase in the AL, which was not statistically significant ($p=0.054$). The difference in our results to those of previous studies may have been due to the ages of the patients, who were much younger in our study. However, subgroup 3, which included patients with mild to moderate myopia, had a 0.012 mm/year rate of increase ($p=0.025$). Gradual elongation of the eyeball may therefore also affect patients with moderate myopia as well as patients with high myopia, although the degree of change was small, and thus of minimal clinical significance.

We analysed factors affecting AL changes in highly myopic eyes: the age, BCVA, baseline AL and anterior chamber depth were all significant in univariate analyses. In multivariate analyses, we anticipated that age and baseline AL would be significant factors; however, only the baseline AL showed a significant association ($p<0.001$). This result could be explained as follows. The mean age of our high myopia group was 40.6±13.4 years, which was relatively younger than that of subjects in previous studies (48.4±12.2 years, Saka et al.; 57.3±13.6 years, Numa et al.). As the eyeball elongates over time, the age may affect the increase in AL more as time goes by. So age would affect the change of AL in relatively older patients more than younger patients. Additionally, subgroups 1, 2 and 3 showed a significant increase in AL over time; however, the degree of change in subgroup 1, which had the longest AL, was six times greater than that in subgroup 3. Although age may be an important factor, the AL at baseline was the factor most strongly associated with subsequent changes therein.

**Study limitations and strengths**

This study had some limitations. First, our participants were relatively younger than those in previous studies, so they may not be representative of all age groups. Second, we did not analyse SE changes because the follow-up period was not enough for analyses of SE changes.

Besides the prospective design, in which there were five measurement timepoints at 1-year interval over a period of 4 years, an additional strength of our study was that it compared AL changes between patients with high myopia and normal subjects. Additionally, we divided the participants into subgroups according to the degree of AL, to observe the association of baseline AL with subsequent changes therein in more detail. Excluding patients with myopic degeneration and including patients with good visual acuity were also strength of the present study with respect to accurately measuring the AL.

In conclusion, myopic eyes, even those with moderate myopia, showed a consistent increase in AL over 4 years. In addition, eyes with a longer AL at baseline showed a greater increase in AL than eyes with shorter baseline AL. This may help explain the positive relationship between a longer AL and various myopic changes, such as chorioretinal atrophy and posterior staphyloma. Based on the results of the present study, we suggest that physicians carefully consider AL increases in patients with high myopia, as these suggest the possibility of myopic degeneration.
