The contralateral upper eyelid in ptosis: some observations pertinent to ptosis corrective surgery

H. K. MEHTA
From the Eye and Cottage Hospital, Caernarvon, Gwynedd, Wales

SUMMARY The validity of Hering's law in corrective surgery for ptosis is demonstrated for the first time. It is also shown how Hering's law has been utilised in corrective surgery for unilateral ptosis to elicit a predominant response from the unoperated contralateral upper eyelid. Other implications of reciprocal innervation of the 2 upper eyelids are discussed and a tentative hypothesis is postulated that in a case of true unilateral levator ptosis the fellow upper eyelid will show compensatory retraction.

Compensatory retraction of the contralateral upper eyelid is a relatively common occurrence in patients with unilateral ptosis of an upper eyelid. But the phenomenon has received scant attention in ophthalmic literature. Evidence is presented here to show that as well as occurring frequently in ptosis this phenomenon also occurs in mechanical ptosis, and that it has the following clinical implications.

Firstly, in some patients this compensatory retraction of the fellow upper eyelid constitutes as much a cosmetic blemish as does the ptosis in the primarily affected eye.

Secondly, just as surgical operation on the extracocular muscles of one eye has effects on the actions of the corresponding muscles of the fellow eye (a phenomenon repeatedly exploited in the surgical management of patients with strabismus), so does a similar phenomenon operate in corrective surgery for ptosis. It can be utilised to 'balance' the position of the 2 upper eyelids, as follows: (a) The improvement of unilateral ptosis by levator resection is frequently accompanied by reduction in the compensatory retraction of the unoperated fellow upper eyelid. (b) In some patients in whom gross surgical overcorrection of unilateral ptosis has caused unsightly ipsilateral upper eyelid retraction the unoperated contralateral upper eyelid develops a compensatory ptosis. When the overcorrection is relieved by levator recession surgery, the compensatory ptosis of the contralateral upper eyelid is also relieved.

Thirdly, in cases of bilateral ptosis, when uni-
retraction of performed under local anaesthesia

A man 3rd nerve palsy, Case 3
A woman aged 54 with severe bilateral acquired ptosis of undetermined aetiology wanted surgical correction because the drooping eyelids severely obstructed her vision (Fig. 4a). One week after a left levator resection of 14 mm and 2 mm tarsectomy there was an improvement of ipsilateral ptosis, but worsening of the ptosis of the right upper eyelid (Fig. 4b). The final satisfactory result after right levator resection is seen in Fig. 4c.

The worsening of the ptosis of the unoperated

and the child were as much concerned about the staring right eye as they were about the ptosis. As there was total absence of Bell's phenomenon, and as the left eye used to remain half open during sleep, when discussing surgical correction it was explained to the parents that full correction of the ptosis might usher in exposure keratopathy, and that a small levator resection of the left upper eyelid would probably not only produce some improvement in the ptosis but also that the right upper eyelid would probably respond by lessening its retraction. The result of a deliberately small levator resection (10 mm) of the left upper eyelid is shown in Fig. 2b.

The improved appearance in this case has been achieved by 3 factors—minimal improvement in the ptosis, formation of a lid fold, and a reduction in the retraction of the right upper eyelid.

Case 3
A man aged 82 when seen in February 1976 had ptosis of the left upper eyelid due to a total left 3rd nerve palsy. He also had gross compensatory retraction of the right upper eyelid (Fig. 3a). Six months later, there being no improvement in the 3rd nerve palsy, a 14-mm resection of left levator

with 2-mm tarsectomy was carried out. The primary aim was to reduce the compensatory retraction of the right upper eyelid, as it was accepted that the paralytic ptosis was unlikely to improve even after the ipsilateral levator resection. The result 3 months after surgery (Fig. 3b) shows the expected reduction of the retraction of the right upper eyelid.
involved the lateral half of the levator palpebrae. Fig. 6 shows the appearance 2 weeks after the repair. Note the mechanical ptosis of the left upper eyelid and retraction of the right upper eyelid.

**CASE 7**
A man aged 73 with herpetic keratitis developed 'mechanical ptosis' of the right upper eyelid and retraction of the left upper eyelid.

**CASE 5**
A 76-year-old man with senile myogenic ptosis of the left upper eyelid did not have a compensatory retraction of the right eyelid (Fig. 5a). Phenylephrine 10% drops were instilled in the left eye only. Ten minutes later there was improvement in the ptosis of the left eye and reciprocal drooping of the upper eyelid of the right eye (Fig. 5b).

The absence of compensatory retraction of the right upper eyelid suggests that possibly this may eventually turn out to be a case of bilateral ptosis.

**CASE 6**
A 60-year-old man was operated on for repair of a laceration of the left upper eyelid which also involved the lateral half of the levator palpebrae. Fig. 6 shows the appearance 2 weeks after the repair. Note the mechanical ptosis of the left upper eyelid and retraction of the right upper eyelid.
The contralateral upper eyelid in ptosis: some observations pertinent to ptosis corrective surgery

Compensatory retraction of the left upper eyelid (Fig. 7).

Discussion

Compensatory retraction of the contralateral upper eyelid in cases of unilateral ptosis was first reported by Walsh (1957) and subsequently by Lewallen (1958), Jain (1963), Gupta et al. (1964), and Gay et al. (1967). They all explained the reciprocity of the levators of the 2 upper eyelids on the basis of a reflex mechanism obeying Hering's law. Kennard and Smyth (1963) demonstrated the presence of stretch receptors in the levator muscles. However, so far there have been no reports of clinical utilisation of Hering's law in corrective surgery for ptosis. Other authors (Table 1), with the exception of Beard (1976), who have reported the results of surgical correction of unilateral ptosis appear to have ignored (by letting pass unremarked) the compensatory posture alteration of the unoperated contralateral upper eyelid despite the fact that in some instances this compensatory response has contributed much to improve the patient's appearance. Similarly, some authors (Mustarde, 1968; Mustardé et al., 1970) studying the effects of instillation of cocaine-adrenaline or guanethidine drops unilaterally into the eye having ptosis have restricted their observations only to the eye under study. However, the photographs in their communication clearly indicate posture alteration of the fellow upper eyelid.

It can be seen from my Cases 2 and 3 of ptosis of poor prognosis that I have utilised Hering's law predominantly to elicit a response from the unoperated contralateral upper eyelid. In my series of unilateral ptosis with contralateral upper eyelid retraction I have opted to perform resection of the levator of the eyelid showing ptosis. But if the validity of Hering's law is to be established for the corrective surgery of ptosis, then, theoretically at least, similar results should be expected to be obtained whether one resected the levator of the
ptosed eyelid or recessed the levator of the retracted eyelid. Evidence for the efficacy of the latter can be judged by the case of Maris reported by Reeh et al. (1976). This patient, like my Case 1, showed unilateral ptosis with retraction of the fellow upper eyelid. Maris considered the ‘hyperelevation’ to be the primary congenital defect in his case and therefore carried out recession of the ipsilateral levator. The postoperative photograph clearly shows compensatory elevation of the contralateral eyelid, which had ptosis. It therefore looks certain that Hering’s law can be used effectively to balance 2 asymmetrically positioned upper eyelids. An obvious and logical corollary of this is in cases of bilateral ptosis, when unilateral corrective surgery for ptosis is carried out. The improvement of ipsilateral ptosis may be accompanied by worsening of the ptosis of the fellow upper eyelid. The patient can be warned about this.

An analysis of my own 20 cases of unilateral ptosis of varied aetiology has shown the presence of compensatory retraction in 19. (The only patient not showing compensatory retraction was Case 5 of this communication.) This leads me to postulate a tentative hypothesis that, if in a case of apparently unilateral levator ptosis there is absence of retraction of the fellow upper eyelid, one is probably not dealing with a true unilateral ptosis but with a potentially bilateral ptosis.
