SUMMARY A prospective randomised study of 26 eyes (24 patients) following uncomplicated intracapsular cataract surgery was carried out with three groups in which different agents were used to re-form the anterior chamber: air, seven eyes; sodium hyaluronate, seven eyes; and a combination of hyaluronate plus systemic acetazolamide, 12 eyes. The intraocular pressure (IOP) was measured by Goldmann applanation tonometry 16 hours before surgery and every eight hours after surgery for 72 hours. The IOP doubled in the two hyaluronate-treated groups for the first day following cataract surgery. By contrast, the IOP in the group receiving air initially decreased slightly. Throughout the study the effect of using acetazolamide was never statistically significant. After the first day and a half the differences in IOP among the three treatment groups disappeared, and the pressures returned to their preoperative values.

Healon is a highly purified, high molecular weight fraction of sodium hyaluronate.† There is evidence that hyaluronate protects the corneal endothelium during anterior segment surgery, and the agent is in wide use.‡ While some investigators have found it to be associated with increased IOP,§ others have found it not or only rarely to be so.‖‖ We report the results of a prospective randomised study of patients undergoing cataract surgery with and without the use of hyaluronate and a third group with hyaluronate plus acetazolamide.

Patients and methods

Routine uncomplicated intracapsular cataract surgery was performed on 26 eyes of 24 patients by four surgical residents between September 1980 and February 1981. The patients were the first 24 consecutive ones without a past or family history of glaucoma, inflammatory ocular disease, or preoperative intraocular pressure (IOP) greater than 20 mmHg. The assignment to the three groups was random except for six patients receiving intraocular lens implantation, who were all treated with hyaluronate plus acetazolamide. Any patient receiving medication necessary for other medical purposes was maintained on that therapy throughout the study or excluded because of possible pharmacological effects on IOP (e.g., corticosteroids, propranolol, etc.). All patients received retrobulbar anaesthesia followed by digital compression of the globe. A fornix-based conjunctival flap was made, followed by a step incision. After peripheral iridectomy, cryoextraction of the lens was performed with the aid of 1 ml of 1:5000 dilution of alpha-chymotrypsin. The two hyaluronate-treated groups received 0·1 ml of Healon to re-form the anterior chamber prior to closure with interrupted 10-0 nylon. Air was used to re-form the anterior chamber in the third group. All intraocular lenses were of the 4-loop, iris fixation type (Intermedics) and were coated with Healon prior to insertion.

The IOPs were determined by Goldmann applanation tonometry about 16 hours before surgery, approximately eight hours (7·1±1·8, mean±SD) postoperatively, and every eight hours thereafter for 72 hours. Each patient’s preoperative IOP was used as his or her own control value.

Several statistical analyses were performed on the IOP data. A two-tailed Student’s t test was done on
Hyaluronate increases intraocular pressure when used in cataract extraction

The mean difference between each IOP after surgery and its preoperative control. These means were also compared in pairs by the *t* test. In addition, analysis of variance was performed on these means for all three groups at each time. To test the variation in the ratio of males to females in the three treatment groups, *x*² analysis was performed. In both the analysis of variance and the *t* test used to compare the means from different groups the variances of the means were tested for homogeneity by Levene’s test for equal variance. Except when these variances differed (*p*<0.01), the variances within groups were obtained from the pooled data. This could be done in all *t* tests comparing hyaluronate with and without acetazolamide and throughout the analysis of variance. A *p* value of 0.01 was used for statistical significance.

**Results**

The preoperative values for the three treatment groups are given in Table 1. There was no statistically significant difference between their age, sex, and IOP.

In one of the patients who had both eyes operated on, the two eyes were randomly distributed to different treatment groups. In this patient the IOP was dramatically raised in the eye receiving hyaluronate but was decreased somewhat in the fellow eye receiving air (Fig. 1). The preoperative control data points shown at time zero were measured 16 hours preoperatively and were used as a constant.

In both the hyaluronate and hyaluronate plus acetazolamide groups the mean difference in IOP from preoperative values was significantly raised during the first two days postoperatively (Table 2 and Fig. 2). The increase was greatest around 16 hours and almost doubled the IOP during the first postoperative day. Thereafter a gradual decline was seen, with no statistical significance after about a day and a half. In the group receiving air an initial decrease in this mean IOP difference was seen at eight hours. Thereafter this difference was no longer significant. A comparison of the mean differences with and without acetazolamide (*t* test) indicated no effect of the acetazolamide (*p*>0.2). After about the first day and a half there was no statistically significant IOP difference among any of the groups (analysis of variance) or between them and their preoperative control values (paired *t* test).

Of the 12 patients receiving hyaluronate and acetazolamide six received intraocular lenses coated with Healon and six received routine, uncomplicated intracapsular cataract extraction. These two groups were not statistically different and their data were therefore pooled. This finding is in agreement with previous studies.11

Discussion

Patients receiving sodium hyaluronate had a marked ocular hypertensive response during the first day and a half postoperatively when compared with preoperative values (Figs. 1 and 2 and Table 2). The maximum IOP occurred around 16 hours postoperatively. In a hyaluronate study using rabbits and cynomolgus monkeys the IOP was shown to peak at approximately three hours, probably reflecting species, age, or experimental differences. The aetiology of the ocular hypertension probably involves the large molecules of hyaluronate creating mechanical resistance in the trabecular meshwork. In a study of enucleated human eyes hyaluronate was found to cause a marked decrease in outflow facility. Hyaluronidase is normally present in the anterior segment, but it appears to have only a negligible role because of the large amount of hyaluronate forced into the trabecular meshwork.

Ocular hypertension associated with cataract surgery is well documented. Kirsch found the incidence of increased IOP (Schiotz >24.4 mmHg) in 72.5% of patients undergoing intracapsular cataract surgery with alpha-chymotrypsin (as used in the present study) compared with only 23.6% of patients not receiving the enzyme. The course of the ‘enzyme’ glaucoma was described typically from days 2 to 5 with recovery by day 7. Actual clogging of the trabecular meshwork with zonular fragments has been reported in eyes treated with alpha-chymotrypsin. Extracapsular cataract extraction may be accompanied by lens debris in the anterior chamber, which may mix with hyaluronate and cause ocular hypertension. Our current method of cataract surgery is an extracapsular extraction with insertion of a posterior chamber lens. It is our clinical impression that postoperative intraocular pressures are higher than we previously observed following intracapsular cataract surgery. Even in patients receiving only saline (i.e., receiving neither alpha-chymotrypsin nor hyaluronate) ocular hypertension was observed as early as six hours after cataract surgery. This has also been observed by others, with IOPs reported to be greater than 30 mmHg. Implicated mechanisms include swelling of the trabecular meshwork and breakdown of the aqueous barrier. These reactions would suggest that the usually observed ocular hypertension follow-

Fig. 2. Mean difference between the IOP at each time after surgery and its preoperative control value for the air (triangles), hyaluronate (circles), and hyaluronate plus acetazolamide (Xs) groups. The SE for each point is given in Table 2.

Hyaluronate increases intraocular pressure when used in cataract extraction

Sir, The present data revealed an initial, transient ocular hypotension in the patients receiving air (Figs. 1 and 2 and Table 2). This may have resulted from the direct effect of air or, possibly, from the relatively long operating times of resident surgeons who performed all the surgery. Long operating times may have caused mild choroidal detachments and hypotony. Brown et al. measured the IOP three hours after cataract surgery in 20 eyes that had received alpha-chymotrypsin and had an air bubble left in their anterior chambers. Their results are suggestive of an early decrease in the IOP (measured at three hours postoperatively). Air, a compressible substance that is absorbed slowly over several days, may damage the endothelium, but the effect appears to be short-lived. It may be that a combination of hyaluronate and air would neutralise the IOP changes, though surgical visualisation is decreased when air mixes with hyaluronate.

The unique physiochemical nature of hyaluronate probably negates the therapeutic value of agents that reduce aqueous secretion (e.g., acetazolamide). Removal of excess hyaluronate prior to closure may prove to be of value, although it did not alleviate the outflow blockage in enucleated eyes filled with hyaluronate. No increase in morbidity was evident in our patients, but the potential for ischaemic retinal and optic disc disease is real. Although hyaluronate is extremely useful in intraocular surgery, we believe that further studies are important to develop appropriate treatment for the raised IOP in patients receiving it.

The patients were all operated on at the Wishard Memorial Hospital, Indianapolis, Indiana, between September 1980 and February 1981. The authors would like to thank John O’Riordan for his advice and assistance with the statistical analyses. This investigation was supported in part by National Eye Institute research grant EY 04085 and a Research to Prevent Blindness research grant professorship (JTE).
