Nasolacrimal obstruction and facial bone histopathology in craniodiaphyseal dysplasia

Dominic A McHugh, Geoffrey E Rose, Alec Garner

Craniodiaphyseal dysplasia is a rare, severe, and progressive bone dysplasia characterised by thickening, distortion, and enlargement of the cranium and face. 1,2 Epiphora and recurrent dacrycystitis can occur in this and other such bone diseases owing to nasolacrimal duct stenosis. 3,4 The management of such a case provided an opportunity to obtain material for analysis, with the aim of gaining more information on the aetiology and possible treatment of this condition.

Case report
The patient was a female, aged 3 years in whom a diagnosis of craniodiaphyseal dysplasia had been made soon after birth, from the typical clinical (Fig 1A) and radiological appearances (Fig 1B).

A low calcium diet had been commenced and calcitriol therapy administered in an attempt to
Histology of the bony fragments obtained during surgery disclosed a thickened periosteum composed of dense, hyalinised fibrous tissue with focal clusters of fibrocytes (arrows). A nerve twig is also seen. (Haematoxylin and eosin, ×115).

Figure 2

Figure 3 Cortical lamellar bone. (A) A remodelled space lined by prominent osteoblasts and containing fibrous tissue infiltrated with lymphocytes. (B) Same field viewed by polarizing microscopy emphasizes the remodelled nature of the lamellar bone. (Haematoxylin and eosin, ×115).

Comment

There are fewer than 20 reported cases of craniodiaphyseal dysplasia. A recessive mode of inheritance has been suggested. The underlying pathology appears to be hyperostosis and sclerosis, predominantly affecting the skull and facial bones. Other skeletal abnormalities include a cylindrical appearance of the long bones and thickening and sclerosis of the ribs, clavicles, pelvis, and spine. Growth may be retarded and sexual maturation delayed. An early death is common.

Bony overgrowth can result in cranial nerve compression, causing visual and auditory impairment and may be associated with headache, mental retardation, or seizures. Craniofacial abnormalities include paranasal bogginess and hypertelorism (Fig 1A), which may cause lacrimal or nasal obstruction, resulting in recurrent lacrimal and respiratory tract infections.

Although the bony abnormalities are usually confirmed by radiological examination (Fig 1B), in this case we were able to provide a histological indication of the underlying pathology (Figs 2 and 3). Although relatively non-specific, they are similar to the morphological findings of Bonucci and colleagues who examined biopsy samples from the frontal bone and iliac rest of a 5-year-old child with craniodiaphyseal dysplasia. Thickened bony trabeculae were observed, which contained variable numbers of osteocytes. The trabeculae were in contact with osteoid seams which contained osteoblasts and osteocytes. A relative lack of calcification was a feature of the samples described.

The effective management of this condition is difficult. Treatment with calcitonin has been reported to result in a fall in the velocity of increase in head circumference and changes in serum and bone alkaline phosphatase. Compression of the cranial foramina may result in brain stem com-
An unusual form of blink reflex induced by pressing on a frontal burr hole

Avinoom B Safran, Gian Luca Lafi, Bertrand Demierre

In a patient with Arnold-Chiari type I malformation and drained hydrocephalus communicans, we observed the unique clinical pattern of a sustained contraction in the orbicularis oculi muscle when pressing on the burr hole. It can be speculated that digital pressure on the dura mater elicited an unusual form of blink reflex. It is also conceivable that this phenomenon was related to a slight increase in intracranial pressure.

Case report

A 60-year-old woman complained of intermittent contractions of the right orbicularis oculi muscle. She presented an Arnold-Chiari type I malformation, with closed Magendie foramen. She had successively undergone a ventriculoperitoneal shunt, numerous external ventricular drainages through a right frontal burr hole, suboccipital craniectomy with C1-C2 laminectomy, and opening of the Magendie foramen. Three years later, she noted narrowing of the right palpebral fissure when pressing with her finger on the scalp overlying the frontal burr hole. She also complained of vertical diplopia and difficulty in walking.

Neuro-ophthalmic examination showed that visual acuity and visual fields were normal. The patient showed signs of left ocular tilt reaction with tilting of the head to the left, left comitant hypotropia 6 dioptres in magnitude, and conjugate leftward cyclotorsion. Corneal sensitivity and resting position of the eyelids were unremarkable. However, when pressing with the finger on the scalp overlying the bone aperture previously made by trephination, a sustained contraction of the orbicularis oculi occurred.

Only the pretarsal fibres of the lower part of the orbicularis muscle were involved. This phenomenon was observed each time, and as long as, digital pressure was applied in the trephination area. Neurological examination further showed slight ataxia and instability without cerebellar syndrome.

Comment

This patient showed a most unusual phenomenon, consisting of a unilateral contraction of orbicularis oculi muscle which occurred when pressing on a burr hole in the frontal bone. The mechanisms which produce this phenomenon are poorly understood. The possibility of a voluntary contraction of the eyelid was discarded because of the sectorial involvement of fibres in the orbicularis oculi muscle. We suggest that the pressure applied on the frontal burr hole irritated an area of the dura mater innervated by the trigeminal nerve, thereby inducing an unusual, segmental form of blink reflex. A second hypothesis, although much less probable, may be considered to explain the occurrence of the lid phenomenon reported here. It is based on a possible increase in intracranial pressure caused by pressure on the burr hole. Indeed, it cannot be excluded that the blinking was a sign of increased intracranial pressure, causing irritation of the facial nerve, even though the rise in intracranial pressure induced by digital pressure was probably moderate. Cranial nerve function is occasionally altered following elevation of intracranial pressure. The most common changes involve the optic and the abducens nerves. In this condition, single cases...
