The histology at 6 weeks was not diagnostic of pyoderma gangrenosum; this biopsy was, however, performed on a healing lesion. From the second biopsy a diagnosis of lymphomatoid papulosis was made (Figs 3 and 4). High dose tetracycline, 1 g twice daily, seemed initially to reduce the number of recurrences and allow recurrent lesions to resolve more quickly. After 4 months, tetracycline lost any apparent effectiveness and low dose methotrexate, 2-5 mg weekly was introduced, with some benefit.

**COMMENT**

The ulcer of pyoderma gangrenosum is usually shallow and solitary, non-tender, and resolves over 5-6 weeks to leave a small shallow ulcer. In previous reviews of 21 cases involved the eyelids. Positive cultures for *Staphylococcus aureus* are usually obtained. All other investigations, including syphils serology, are negative.

Lymphomatoid papulosis was first described by Macalady as a chronic, recurrent, self-healing, papulonodular or papulo-necrotic eruption, "histologically malignant but clinically benign". The lesions regress spontaneously over several weeks, but recur every few months. Investigations are essentially normal.

Ten per cent of patients with lymphomatoid papulosis may develop a cutaneous or systemic lymphoma, including mycosis fungoides, Hodgkin's disease, lymphocytic lymphoma, large cell lymphoma, and lethal midline granuloma. There are no predictive markers for this progression. The presence of atypical cells against a setting of follicular mucinosis has until now been routinely associated with a cutaneous T cell lymphoma. So far the patient has exhibited self-healing necrotic lesions only. Whether the presence of follicular mucinosis in this situation will turn out to be a poor prognostic sign remains to be seen.

The treatment of these patients is unsatisfactory. Steroids and antibiotics are ineffective. Complete, but often transient, remissions have been achieved with electron beam therapy, combination chemotherapy, PUVA, and methotrexate. Long term follow up is mandatory.

Although four cases of follicular lymphomatoid papulosis have been reported, to our knowledge this is the first report of follicular mucinosis in lymphomatoid papulosis and the first report of bilateral symmetrical eyelid involvement as the presenting feature of this condition.

**Human papilloma virus DNA detected in case of inverted squamous papilloma of the lacrimal sac**

**EDITOR.—** We present the first known report in which an inverted squamous papilloma of the lacrimal sac was associated with human papilloma virus (HPV). While squamous papillomas of the nasal cavity and paranasal sinuses are not uncommon, an inverted squamous papilloma that originates in the epithelium of the lacrimal sac is rare. Inverted papillomas of the lacrimal sac often reveal areas of invasive acanthosis of surface epithelium into the underlying stroma and show foci of carcinoma or foci that develop into carcinoma. We present a young patient with inverted squamous papilloma of the lacrimal sac in whom we identified HPV antigen and DNA within the dysplastic lesion.

**CASE REPORT**

A 26-year-old Japanese woman who had noticed 15 months earlier a painless swelling of the left lower eyelid that gradually increased in size was admitted to our clinic. She presented with a medial canthal mass associated with epiphora and discharge. Magnetic resonance imaging (MRI) revealed a lobular tumour that totally filled the lumen of the left lacrimal sac (Fig 1). On 9 July 1993, the tumour was resected under general anaesthesia. The solid tumour found within the lacrinal sac appeared to be continuous with the nasal cavity, preventing its total removal from the bony tract of the naso-lacrimal duct. Postoperative MRI examination 2 months later showed no residual tumour within the nasolacrimal duct. Macroscopically, the tumour showed a lobular pattern and was surrounded totally by the...
lumen of the lacrimal sac. Histologically, we observed an inverted squamous cell papilloma with dysplastic change, marked mitotic activity, and koilocytosis in the cells near the tumour surface (Figs 2, 3). The superficial epithelial tumour cells were positive for anti-HPV antibody (Dako Corporation, USA) by immunohistochemical staining (Fig 4). Cells were also positive for a wide spectrum HPV fluorescein labelled DNA in situ hybridisation probe (Dako Corporation, USA) including types 6, 11, 16, 18, 30, 31, 33, 35, 45, 51, and 52 HPV (Fig 5). Cells were negative for a type 6/11 probe. Fluorescein staining of the nuclei of tumour cells was stronger in the superficial epithelial cells than the deeper cells. Follow up at 10 months showed no clinical or radiological evidence of any recurrence.

COMMENT
Primary tumours of the lacrimal sac are rare. Most of them are benign, including adenomas and papillomas. The latter may be exophytic or inverted. Inverted papilloma can be readily transformed into carcinoma, even in a young adult. Anderson et al recently reported a 56-year-old patient with transitional cell carcinoma arising from an inverted papilloma.2 In our case, epithelial dysplasia that displayed cytoplasmic clearing along with nuclear pyknosis and koilocytosis suggested HPV infection as an aetiology, since koilocytosis in squamous papilloma is commonly found in lesions associated with HPV.3 Based on the histopathological findings in this case, we conducted an immunohistochemical and molecular biological investigation of HPV in the lesion, which revealed HPV DNA. Previous studies have shown that ocular conjunctival squamous papilloma may be related to HPV types 6 and 11, and squamous dysplasia or carcinoma to HPV types 16,18,19 HPV antigens and DNA types 16, 18, 31, 33, and 35 have been identified within squamous dysplastic changes or carcinomas affecting the female reproductive tract.4 Such findings suggest an oncogenic potential of HPV infection. In the present case, HPV was, thus, probably responsible for squamous papilloma with dysplastic changes of the lacrimal sac. The mode of transmission of HPV to the epithelium of the lacrimal sac is unknown, but it could occur during passage of a fetus through the infected birth canal. 

Ophthalmologists should be alert to the possibility of HPV infection, especially in a young adult with lacrimal sac papilloma, as this disorder may have oncogenic potential.

Multiple molluscum contagiosum lesions of the limbus in a patient with HIV infection

EDITOR,—In HIV infection, molluscum contagiosum of the eyelids is quite common, but limbal molluscum contagiosum is rare. We report a documented case of multiple bilateral molluscum contagiosum of the limbus in an HIV seropositive patient.

CASE REPORT
A 40-year-old African (Zaire) man presented with bilateral ocular foreign body sensation which had developed 1 month earlier, without signs of the eyes or loss of vision. The patient tested seropositive to HIV 4 years earlier and had not developed any AIDS defining illness so far. He had been treated by repeated curettage and cryotherapy for over a year for disseminated molluscum contagiosum lesions of the skin, localised mainly on the face, the trunk, and the genitalia. CD4 T lymphocyte count at the time of ophthalmic evaluation was 70×10⁶/µl. Visual acuity was 20/20 in both eyes without correction. Slit-lamp examination revealed multiple, confluent, molluscum contagiosum lesions on the skin of the four eyelids. On the limbus of the left eye, two white mulitlobular lesions, 4 and 1 mm in diameter, were noted at 6 and 1 o'clock respectively (Fig 1). Another similar lesion, 2 mm in diameter, was present on the limbus in the right eye, at 3, 4, and 6 o'clock. The lobules of these lesions, encroaching on to the cornea, were dome-shaped with a slight central umbilication. There was a mild perilimbal conjunctival injection around each limbal lesion. Anterior chamber, vitreous, and fundus examinations were normal in both eyes. An excisional biopsy of the largest lesion in the left eye was performed. Histopathological examination was consistent with the diagnosis of molluscum contagiosum (Fig 2). It showed a hyperkeratosis and hyperkeratosis of the epithelium, an oedema of the underlying intercellular space, and numerous swollen cells containing cosinophilic intracytoplasmic inclusions (‘molluscum bodies’). Three months after the biopsy, the excised lesion had not grown back, but the other limbal lesions of both eyes remained unchanged despite no treatment. In both eyes, no new conjunctival, limbal, or corneal lesions were seen and the foreign body sensation was stable.
