Ocular signs associated with a rhodopsin mutation (Cys-167→Arg) in a family with autosomal dominant retinitis pigmentosa

Editor,—Retinitis pigmentosa (RP) comprises a group of hereditary progressive retinal degenerative conditions characterised by typical fundus alterations, loss in visual field, and severely reduced or unrecordable electroretinograms (ERG). The first reported disease related mutations in the human rhodopsin gene, described in 1990 by Dryja et al, was a heterozygous C→A transversion in the second nucleotide of codon 23. Since then many further mutations have been identified to a current total of about 90.

Here we describe, for the first time in the literature, the clinical phenotype associated with a Cys-167→Arg mutation (TGC→CAG in exon 2) in an Italian family affected by autosomal dominant retinitis pigmentosa (ADRP). The same mutation was noted by Dryja et al, but there has been no report of correlated clinical data.

CASE REPORT

Four patients (see Fig 1) of a family from the Campania region of southern Italy, have been studied.

Patient II-1

The patient, a 45 year old woman, had central visual acuity 20/50 in both eyes with −3 −3 ° and −4 −2.50 ° respectively. Fundus examination revealed waxy optic disc pallor, attenuated retinal vessels, atrophic retinal pigment epithelium (RPE), and bone spicules in the middle periphery on 360° (Fig 2). Goldmann kinetic visual field examination showed a concentric isoptere shrinkage up to 10° in the centre in each eye (I and II,4). No peripheral vision island was observed. Goldmann–Weekers adaptoperimetry examination showed a high depression of the photopic and scotopic curve in both eyes. Electroretinography showed no photopic and scotopic curve. Acromatopsy was found in the colour test.

Patient III-2

This patient, a 8 year old male showed a corrected visual acuity 20/25 in both eyes with +1.50 × 100° in the right and left eye. The fundus, Goldmann visual field and the Goldmann–Weekers adaptoperimetry examination are similar to the patient III-1. ERG showed a microvolt photopic graph with implicit time of the a wave equal to 32 ms and implicit time of the b wave equal to 52.20 ms, with a differential width of 10.75 µV. The scotopic graph was extinguished.

Patient III-3

This patient was male first examined at 16 months. Fundus examination showed atrophic RPE changes and bone spicules in mild periphery. At age 7, he was re-examined and found to have a corrected visual acuity of 20/25 in both eyes with +1. Goldmann visual field examination showed a marked reduction in retinal sensitivity in both eyes, especially in the nasal sectors. ERG showed a microvolt photopic graph with an implicit wave time of 52.40 ms and an implicit b wave time of 53.70 ms, with a differential width of 14.7 µV. The scotopic graph was extinguished.

COMMENT

This study has correlated a mutation Cys-167→Arg of the rhodopsin gene with phenotypic type I in an Italian family. The mutation segregated with the clinical disease, and all affected patients showed a similar phenotype. The disease has a very early onset: in the youngest subject the diagnosis was made at 16 months of age. The first symptoms in all subjects were night blindness and visual field shrinkage (restricted side vision). Examination of the fundus of the eye identified a typical RP form, with vessel narrowing and osteoblast-like pigmentation in the middle retinal peripheral area in four sectors.

Atrophic changes of the RPE in the macular region and in the middle periphery were identified only in the patient II-1. Electroretinography showed an early alteration of retinal function, whereas cone function was not completely compromised until almost age 18. Clinical examination repeated yearly for up to 7 years in three subjects indicated that the disease progresses very slowly.

Furthermore, the exact mechanism involved in affecting the visual cycle is difficult to imagine. Cysteine at position 167 of the rhodopsin gene is highly conserved during the evolution of mammals, but it is not known whether apoptosis is involved in all the forms of induced or degenerative photoreceptor death. Such mechanisms are just coming under scrutiny.

The authors would like to thank the family for its contribution to these studies. The authors were also grateful to Professor G Imbucci, of ORAO association; A Terracciano for technical assistance, and to Servizio di Tecnologie Biomolecolari, Area di Ricerca CNR Naples, where the sequences were performed. This work was supported by Telethon-Italy, grant no ES46 to AC and CNR grant no CTR.94.2863 to ER; MGM is a Telethon-Ithony fellow.

Haemangiosarcoma of the breast, metastatic to the ciliary body and iris

Editor,—Angiomatous tumours of the ciliary body and iris are very rare. Even metastatic foci of angiosarcomas are not seen often in this location. This is why we are publishing our case of disseminated haemangiosarcoma
with metastatic involvement of the ciliary body and the iris. The eye maintained useful function until the patient's death 1 year after the appearance of the focus in the eye.

CASE REPORT
Clinical observation
A 53 years old woman was admitted to our eye clinic for deterioration of vision in her left eye and headaches. A tumorous focus involving the ciliary body and the radical part of the iris was revealed both clinically by ultrasound and with magnetic resonance imaging (MRI). The tumour had grown laterally at the 3 o'clock position (see Fig 1A and appeared to have a solid structure. The diameter of its base was about 6 mm. The vision was 6/12 when the patient was first examined but quickly deteriorated to light perception only, because of the blood in the anterior chamber. After removal of the blood from the anterior chamber, the vision improved again to 6/12. The intraocular pressure was normal (18–20 mm Hg) at all times.

Haemangiosarcoma of the right breast treated by ablation and actinotherapy was noticed in the patient's medical history. The original tumour had grown within the breast stroma. Its diameter was about 3–4 cm. The histological pattern varied from relatively well formed vascular channels surrounded by multilayering endothelium to poorly differentiated solid areas formed by poorly differentiated cells with frequent mitoses. Epithelioid differentiation was not noticed. Some areas were haemorrhagic. There were no risk factors for angiosarcoma such as previous radiotherapy2 in the patient's history. The patient was HIV negative. Because of tumourous dissemination in the skin and brain, ocular surgery was abandoned. Removal of blood from the anterior chamber was necessary once more before the patient’s death, 1 year later; otherwise, chemotherapy remained the only suitable treatment. However, the intraocular focus stopped its macroscopical growth and even partly regressed after chemotherapy by cyclophosphamide and vincristine (compare Fig 1A and B). The eye maintained useful function with measurable vision for 1 year until the patient's death due to haemorrhage from metastasis in the brain at the end of July 1993. Postmortem examination of the left eye confirmed histologically the haemangiosarcomatous origin of the intraocular focus.

Histopathology
Gross examination of the eyeball
The enucleated left eyeball measured $23 \times 23 \times 22$ mm with 4 mm of optic nerve. The pupil was slightly oval owing to lateral pressure on the nasal side. Transillumination and opening of the globe revealed approximately half rounded infiltrate which involved the lateral part of the ciliary body (see Figs 1B and 2A). The centre of this infiltrate was at the 3 o'clock position, its vertical diameter was 5 mm and horizontal diameter was 3.5 mm. The aqueous and vitreous were clear.
Histology

The tumorous focus seen in the figures is apparently of an angiomatous nature, and involves only the ciliary body (see Fig 2A and B). Cellular atypias, mitoses, and several haemorrhages are observable within the tumour (see Fig 2A and B). No clearly tumorous structures are present in the radical part of the iris (1 year before death there was a clinically observed and documented expansion of the tumour (see Fig 1A)). There is no marked growth of tumorous tissue from the focus within the ciliary body to the other surrounding structures of the eye. There is angle closure in the region of the tumour as a result of larger anterior synechiae (see Fig 2A). However, the angle of the anterior chamber remains narrow and without closure for the major part of the circumference of the anterior chamber. The other parts of the globe are without remarkable macroscopic or histopathological abnormalities.

COMMENT

Angiomatous tumours of the iris and ciliary body, both primary and secondary, are reported generally as very rare. Even in the breast angiosarcoma is a relatively rare tumour. After histological examination, the angiosarcomatous nature of the described tumorous focus was confirmed. The rarity of this type of intraocular tumorous metastasis focus makes this case remarkable. The secondary intraocular foci of various carcinomas are reported more often. Some rules observed in cases of intraocular metastatic cancer are common with other histological types of malignancies. Metastatic foci in the anterior segment of the eye are reported as much more rare than in the posterior segment. On the other hand, the breast (our case) and the lung are the most frequent primary sites of the intraocular metastases. Median survival time of patients with metastasis to the anterior segment is only 5.4 months, which is significantly worse than with metastasis to the orbit (15.6 months) or posterior pole of the eye (7.2 months). The overall survival of patients with any form of angiosarcoma is very limited. Since survival of our patient was 1 year after diagnosis of the intraocular metastasis, chemotherapy seems to have been relatively beneficial for our patient. 4

Persistent pupillary membranes

Editor—Persistent pupillary membranes (PPMs) which are large enough to interrupt the visual axis are uncommon. If left untreated they may cause stimulus deprivation amblyopia. 1 There is evidence that early treatment to remove obstructions of the visual axis in infants may minimise the risk of amblyopia. 2 We report a case of bilateral persistent pupillary membranes which were successfully treated surgically before the patient was 6 weeks old.

CASE REPORT

A healthy baby induced at 41 weeks was born by normal vaginal delivery following a normal pregnancy. He weighed 8 lb 8 oz (3.8 kg) and was noted to have an abnormal red reflex from both eyes on routine ophthalmic check by a paediatrician before discharge from hospital after birth. He appeared to fix briefly on a light but did not really look at toys. The red reflexes were significantly reduced centrally and there were peripheral spoke-like opacities. Even with dilatation only a poor fundal view was obtained. The view was particularly poor on the right eye. An ultrasound scan of the posterior pole was normal for each eye. Further examination under anaesthetic showed that the child had bilateral persistent pupillary membranes in both eyes (Fig 1). Blood could be seen flowing through the blood vessels within the membranes under the operating microscope. There were no other abnormal examination findings. Screening tests for toxoplasmosis, cytomegalovirus, rubella, and treponemal antibodies were all negative. There was no known history of substance abuse by the mother. The visual axis especially on the right side was significantly obstructed and when the pupils were dilated and consequently we thought that the risk of stimulus deprivation amblyopia was high if they were left in place. The membranes were removed from the right eye when the child was 4 weeks old and from the left eye when he was 5 weeks old.

The same operative technique was used for each eye. A small superior corneal section was made and a further side incision was made. Provisc (Healon) was injected between the membrane and the lens in order to protect the lens from coming into contact with the surgical instruments. Intracapsular diathermy of the membrane vessels was attempted but this failed to have any effect. The membrane strands were cut with vitreous scissors and the freed membranes were removed with macroforceps. There was a small amount of bleeding from one of the more vascularised strands of membrane but the other smaller vessels retracted without bleeding. The Provisc was removed with a Simeo irrigation/aspiration canula. The corneal wounds each required a single 10/0 nylon suture which were removed under anaesthetic 3 months postoperatively.

The visual axis was clear following surgery and there was no evidence of cataract. Histology showed a thin membrane of spindle-shaped cells some of which were pigmented. A fine network of blood vessels extended through the membrane.

Follow up of the child 5 months after the operation revealed no evidence of cataract formation in either eye. The eyes were straight and visual assessment showed that he objected to occlusion of each eye equally with a binocular acuity of 6/10 using Cardif cards.

COMMENT

Remnants of pupillary membranes are very common occurring in 95% of normal newborn babies. Early development of the crystalline lens at about the sixth week coincides with the growth of the tunica vasculosa lentsis which nourishes it. The anterior portion of this is continuous with the pupillary membrane which draws its blood supply from the capillaries which arise from the branches of the long posterior ciliary arteries and the major arterial circle. The pupillary membrane is fully developed by 9 weeks' gestation. These blood vessels begin to undergo remodelling and regression in a process involving phagocytosis by macrophages at around 5 months' gestation. Dysfunction of macrophage invasion and phagocytosis is thought to play a role in the pathogenesis of PPMs. PPMs are thought to be derived from the tunica vasculosa lentis (TVL) and have normally disappeared by the 34th week of gestation. These membranes are often observed by neonatologists as they are frequently seen in premature babies. They can be used to identify the gestational age of a newborn infant (between 27 and 34 weeks) and they...
continue to regress at the same rate as if the child had not been born prematurely. There is some more recent evidence that intrauterine stress, particularly from chronic maternal hypertension, may accelerate the disappearance of these membranes. Some authors believe that hyperplastic after birth rather than congenital idiopathic microcoria which results from underdevelopment of the dilator pupillae. Although not commonly associated with any other pathology there has been a previous report of positive toxoplasma serology occurring in a 30 week premature baby with PPMs. There has also been a report of PPMs occurring in an infant with congenital rubella virus. We believe that any child with a congenital abnormality of the anterior chamber should be screened for possible intrathecal infections. A series of five cases of persistent membranes associated with congenital dystrophy myotonica have been described. There have also been reports of PPMs occurring with a variety of other abnormalities of the anterior chamber which in some cases seem to be familial with autosomal dominant inheritance but in our case there was no family history. There have been case reports of spontaneous haemorrhage occurring form PPMs but these are unusual.

When present PPMs are usually so small as to make no treatment necessary as they shrink significantly over the first year of life. There is some evidence that not all PPMs behave in this way. Some membranes appear to become more hyperplastic after birth rather than resolving. Some authors believe that hyperplastic membranes should be considered as a distinct type of PPM and that they may be less likely to regress than thinner membranes that appear similar to be persistent rather than hyperplastic although no formal study has looked at this.

Smaller membranes than the ones we report have been successfully treated with mydriatic therapy until spontaneous involution occurred. However, the smallest useful pupil aperture is thought to be 1.5 mm without which normal visual development is unlikely to take place. In our patient the visual axis, especially on the right side, was significantly obstructed even though the operator must be aware of the risk of inducing cataract from unnecessary contact with the lens.

There is growing evidence that the severity of deprivation amblyopia is minimised by earlier treatment to remove any obstruction to the visual axis particularly in the case of unilateral congenital cataracts. It is likely that a similar critical period applies to bilateral visual obstruction. Some authors feel that there is no visual advantage to be gained by removing these membranes after the sensitive period for visual development is over although modest improvements have been reported in teenagers.

If bilateral membranes are large enough to put a child at significant risk of amblyopia then it is our view that surgical therapy to this condition should be taken within the first 5 weeks of life as after this time the amount of irreversible visual dysfunction from amblyopia may well increase. Patients treated surgically for this condition should be followed up carefully because of the long term risk of developing cataract, amblyopia requiring patching, and glaucoma which may accompany congenital abnormalities of the anterior segment.

white mass, initially 0.75 mm in diameter, appeared elsewhere on the host endothelium (Fig 2). A subsequent culture again confirmed Candida glabrata.

Amphotericin B 10 µg in 0.1 ml was injected into the anterior chamber, with subconjunctival injection of amphotericin B 300 µg in 0.5 ml. Topical amphotericin B 0.15% 1 hourly and prednisolone 1% 2 hourly were given. Both injections were repeated at 3 and 20 days. The uveitis settled, topical amphotericin was discontinued, and the graft remains clear 2.5 years later on prednisolone drops once daily.

No toxic effects have been noted from intracameral or topical amphotericin B.

COMMENT

Endophthalmitis flared up twice associated with intensive topical and/or oral steroid. Candida glabrata was cultured from the transport medium and the recipient anterior chamber, implicating the donor cornea as the source of infection. Candida glabrata is a relatively resistant organism and treatment was guided by antifungal susceptibility testing of the isolate. This suggested that the isolate was resistant to fluconazole (minimum inhibitory concentration, MIC >128 mg/l) and itraconazole (MIC 16 mg/l), but was of intermediate sensitivity to econazole (MIC 1 mg/l and 4 mg/l variably on different tests) (Table 1). The latter may explain econazole’s failure to prevent infection becoming established. Although the isolate was sensitive to amphotericin B (MIC <0.25 mg/l) this was avoided as prophylaxis because of potential toxicity; however, we accept that some cases may go unreported, this can be compared with an overall incidence of postoperative endophthalmitis in the literature of 0.1–0.8%.8–10 After corneal grafting with corneas stored at 4°C, and of 0.09%,11 following extracapsular extraction.

This patient remained asymptomatic throughout, with intensive topical and/or oral steroid.

Bilateral orbital fat prolapse in cuts laxa

Eptier—The association of ocular abnormality with cuts laxa has been described, but in the case of this child, it was noted that the condition involved not only the eyes, but the whole body. The patient presented with a large, mobile, pale yellow mass at the lateral canthus of each eye, but more prominently on the right (Figs 1 and 2). The overlying conjunctiva was mobile and neither mass had a visible posterior limit. There was no history of previous periocular pathology, trauma, or surgery and ocular examination was otherwise normal.

Incisional biopsy of each mass was performed under local anaesthetic to relieve irritation. The tissue was located in the sub-Tenon’s space and continuous posteriorly with intracanal orbital fat. Histological examination revealed normal adipose tissue without dermal elements.

COMMENT

Cuts laxa (generalised elastolysis) is characterised clinically by generalised lax pendulous skin which hangs in redundant folds and recoils only slowly after stretching.2–3 Histologically, there is sparsity, fragmentation, and aggregation of elastic fibres in the dermis.3,4 Possible pathogenic mechanisms are increased tropoelastin degradation and reduced elastin production—skin fibroblasts have diminished mRNA for elastin in some patients.5

Cuts laxa may be inherited (autosomal dominant or recessive) or acquired.6 In the commoner, recessive form, characteristic facies have downward slanting palpebral fissures, a broad flat nose, sagging cheeks, and large ears producing a bloodhound or prema-
turely aged appearance. Herniae, diverticula, pulmonary emphysema, cor pulmonale, and aortic aneurysm are important complications resulting from abnormal elastic fibres. Acquired forms of cutis laxa may follow inflammatory skin disease or may be associated with hypersensitivity reactions, multiple myeloma, systemic lupus erythematosus, amyloidosis, or maternal penicillamine therapy.2

Tenon’s capsule normally separates intracocular and extraocular orbital fat from sclera. Surgical or traumatic dehiscence of the capsule more than 10 mm from the limbus may allow forward prolapse of intracanal fat beneath Tenon’s capsule.4 In the elderly, fat prolapse may occur without such an antecedent event and is more frequently located superotemporally.45 Orbital fat prolapse is usually diagnosed clinically,5 but may be mistaken for a dermolipoma, dermoid cyst, lacrimal gland tumour, infiltration or granuloma, extraocular muscle enlargement, or an orbital lymphoid proliferation.6,7

The largest case series of orbital fat prolapse reports 15 patients aged between 49 and 94 years (average 65 years) of whom 33% were affected bilaterally. The case we report is significantly younger. Although the occurrence bilaterally of this finding at a young age may be coincidental, it suggests that abnormal elastin in Tenon’s capsule allowed it to dehisce, creating a route between intracanal fat and the sub-Tenon’s space. This report suggests an association between cutis laxa and orbital fat prolapse.
