Results of small incision extracapsular cataract surgery using the anterior chamber maintainer without viscoelastic

Mark Wright, Hector Chawla, Alistair Adams

Abstract

Aims—To assess the efficacy of extracapsular cataract surgery using the anterior chamber maintainer (ACM) without the use of viscoelastic. To compare the effects of this surgical technique on non-diabetic and diabetic patients.

Methods—A prospective single armed clinical trial of 46 eyes in 46 patients undergoing cataract surgery using the ACM without viscoelastic. Patients were assessed preoperatively and at 3 weeks, 3 months, and 12 months postoperatively. The main outcome variables included visual acuity, surgically induced astigmatic change (SIAC), changes in endothelial cell density (ECD), and morphology affecting the central and superior regions of the cornea.

Results—Postoperatively, 56% and 70% of patients had unaided visual acuities of 6/12 or better at 3 weeks and 3 months respectively. Even after excluding those patients with pre-existing maculopathy (including diabetic maculopathy), there remains a significant difference between the non-diabetic and diabetic groups in terms of the proportion of patients attaining an unaided visual acuity of 6/12 or better at both 3 weeks (p=0.003) and 3 months (p=0.001). Three months postoperatively, the SIAC based upon the keratometric and refractive data was 1.1 dioptres (D) and 1.3 D respectively. There was no statistically significant difference in the SIAC when the non-diabetic and diabetic groups were compared. The mean central and superior endothelial cell losses at 3 months postoperatively were 16% and 22% respectively and at 12 months postoperatively were 20% and 25% respectively. The diabetic group demonstrated greater endothelial cell losses and a more marked and protracted deviation of endothelial cell morphology from normality when compared with the non-diabetic group; however, the differences did not reach statistical significance.

Conclusions—The efficacy of small incision cataract surgery using the ACM in terms of visual outcome and induced astigmatism is comparable with the results obtained using other techniques that utilise a similar size of incision. However, in view of the magnitude and range of the endothelial cell losses associated with this technique the concurrent use of viscoelastic substances is suggested. There does not appear to be a statistically or clinically significant difference between non-diabetic and diabetic patients in terms of the magnitude of the endothelial cell losses or in the wound healing response in the 12 months after cataract surgery using the ACM.

The success of cataract surgery is now often measured by both doctors and patients in terms of the postoperative unaided visual acuity. Visual outcome continues to improve as small incision surgery evolves, with phaco-emulsification emerging as the most popular technique. Blumenthal et al have described the use of the anterior chamber maintainer (ACM) allowing small incision cataract surgery to be performed without the use of viscoelastic agents or phacoemulsification. As far as we can ascertain, however, there have been no published reports assessing the effects of this particular technique of cataract surgery on the corneal endothelium.

The purpose of this study was to assess the efficacy and safety of the authors’ modifications of Blumenthal’s “Mini-Nuc” technique and to compare its effects on both non-diabetic and diabetic patients.

Patients and methods

After informed written consent was obtained, 46 eyes from 46 subjects were entered into a single centre, single surgeon (HBC), single observer (MW), prospective single armed clinical trial of patients undergoing extracapsular cataract extraction (ECCE) and intraocular lens (IOL) implantation using the ACM. Viscoelastic substances were not used. Follow up was complete in 42 of 46 eyes (one patient died before his first postoperative visit, a further two died and one other patient was lost to follow up between the 3 and 12 month visits).

Exclusion criteria included previous intracocular surgery, significant corneal opacification, uveitis, glaucoma, or ocular hypertension. Of the study group as a whole, 17/46 (37%) were diabetic, 13/17 had non-proliferative diabetic retinopathy, and 4/17 had proliferative diabetic retinopathy.

The surgical technique has previously been described in detail. Essentially, paracentesis stab incisions were positioned at 2, 4, and 10 o’clock. Balanced salt solution containing adrenaline (1 mg/l) was continuously infused through a self retaining 20 gauge ACM (Visitec...
Wright, Chawla, Adams

The mean patient age was 72 years; 28/46 (61%) were female and 33/46 (72%) of the patients had a BCVA of less than or equal to 6/12 preoperatively.

**Visual outcome**

At 3 weeks postoperatively, 24/43 (56%) had unaided visual acuities of 6/12 or better (one patient died before his 3 week visit and a further two patients were intentionally left with between 3 and 4 dioptres of ammetropia postoperatively and were therefore excluded). At 3 months postoperatively, 30/43 (70%) had unaided visual acuities of 6/12 or better (two patients required laser capsulotomy at 3/12 and were included). No patient required suture removal.

None of the patients (3/45) who had BCVAs of less than 6/12 suffered intraoperative or postoperative complications and all had incidental reasons for their poorer visual outcome; age related maculopathy, diabetic maculopathy and a supratemporal branch retinal vein occlusion, both of which were noted preoperatively.

There was no significant difference between the non-diabetic and diabetic groups in the proportion of patients attaining a BCVA of 6/12 or better (p=0.244). If, in addition to the two patients with deliberate postoperative ammetropia we also exclude the patients with pre-existing maculopathy (including diabetic maculopathy), there remains a significant difference between the two groups in terms of the proportion of patients attaining an unaided visual acuity of 6/12 or better at both 3 weeks (p=0.003) and 3 months (p=0.001).

**Surgerically induced astigmatic change (SIAC)**

Three months postoperatively, the mean SIAC based upon the keratometric data (n=44) was 1.1 D (SD 0.6, range 0.1–2.7). When the refractive data (n=35) were analysed, the corresponding figures are 1.3 D (0.8, 0.1–3.0).

There was no statistically significant difference in the SIAC when the keratometric or refractive data were compared (p=0.288). There was no statistically significant difference between the non-diabetic and diabetic groups in the SIAC for both the keratometric (p=0.127) and refractive data (p= 0.400).

**Surgerically induced endothelial change (SIEC)**

Analysis of the endothelial data from the central region of the contralateral (control) eye was used to validate the repeatability of the method of measurement. The mean central ECD of the control eyes which did not undergo surgery during the study period (n=34) was 2185 (SD 545) cells/mm² (range

992–3236) “preoperatively”; 2169 (536) cells/mm² (912–3125) at 3 months; and 2179 (564) cells/mm² (977–3067) at 12 months “postoperatively”. There was no significant difference when the “preoperative”, 3, and 12 months “postoperative” measurements were analysed (p=0.0001).

The data from the operated eyes are depicted in tabular form. The SIEC from the central region of the cornea is shown in Tables 1 and 2. The SIEC from the superior region of the cornea is shown in Tables 3 and 4. The surgically induced morphological changes in the endothelium were described by the COV in cell size and the percentage of hexagonal cells. The changes in the COV in cell size from the central (c) and superior regions of the cornea are shown in Table 5. The change in the percentage of hexagonal cells from the central (c) and superior regions of the cornea is shown in Table 6.

INTRAOCULAR LENS POSITION
Patients were dilated at the 3 month visit when the position of the IOL was confirmed: 31/45 (69%) of the IOLs were confirmed to be in the capsular bag, 13/45 (29%) were sulcus fixated, 1/45 (2%) was half in half out.

POSTERIOR CAPSULAR OPACIFICATION
Significant posterior capsular thickening (requiring laser capsulotomy) occurred in 2/45 (4%) of cases at 3 months and a further 1/42 (2%) at 12 months postoperatively.

COMPLICATIONS
Surgery was uneventful in 42/46 (91%) and capsular rupture and/or vitreous loss occurred in 4/46 (9%) of cases. The IOP was measured between 16 and 24 hours postoperatively; the mean rise in IOP was 6 mm Hg with the highest IOP measured at 45 mm Hg (following uncomplicated surgery). No patient had raised IOP at either of the two postoperative visits. Superior iris atrophy was observed in 5/46 (11%) of patients postoperatively.

Discussion
VISUAL OUTCOME AND REFRACTIVE CHANGE
The proportion of the patients in this study with uncorrected visual acuities of 6/12 or better at 3 weeks and 3 months after surgery were 56% and 70% respectively. Steinart et al reported that following phacoemulsification using incisions of 4 and 6.5 mm, 62% and 57% of patients at 5 weeks and 70% and 67% of
patients at 3 months had uncorrected visual acuities of 6/12 or better. The induced astigmatic cylinder in our study was 1.1 D which is again comparable with Steinert's figures (based upon keratometric data) of 0.82 D and 1.03 D.

When the visual outcome of the diabetic and non-diabetic groups are compared, the similarity between the two groups in terms of the BCVA is explained by the low prevalence of diabetic maculopathy in our study group; however, we cannot offer a satisfactory explanation for the disparity observed in the unaided visual acuity.

**CHANGES IN ENDOTHELIAL CELL DENSITY AND MORPHOLOGY**

The mean intersession variability in the measurements of the ECDs of the unoperated (control) eye was <1% indicating a high degree of repeatability which is in keeping with the results of other studies. There was no significant regional variation (central vs. superior) in the mean ECD preoperatively (p=0.799). Postoperatively, all eyes demonstrated vertical endothelial cell disparity at both the 3 and 12 month visits with greater endothelial losses found superiorly towards the site of the incision. The mean central and superior endothelial cell losses at 3 months postoperatively were 16% and 22% respectively and at 12 months postoperatively were 20% and 25% respectively. Depending upon the technique of phacoemulsification employed and the type of viscoelastic used the reported mean central endothelial cell losses range from 4% to 14% at 3 months postoperatively. Similarly, the mean superior endothelial cell losses range from 8% to 16% between 12 and 24 months postoperatively. Modern extracapsular surgery using viscoelastics results in central endothelial cell losses of approximately 15% at 3 months postoperatively.

The range in the magnitude of the endothelial cell losses was considerable, with five patients (11%), despite having undergone uncomplicated surgery demonstrating endothelial cell losses which were greater than twice the mean. These patients did not differ from the study group as a whole in terms of the prevalence of diabetes.

The mean central endothelial cell losses (combined 3 and 12 month data) of the group of four patients who had posterior capsular tears and/or vitreous loss was 14% which compares favourably with the equivalent figure of 18% for the group undergoing uncomplicated surgery. The mean superior endothelial cell losses for the same two groups were 22% and 23% respectively. The mean central endothelial cell losses (combined 3 and 12 month data) of the group of five patients who were noted postoperatively to have superior iris atrophy was 34% compared with cell losses of 16% in those patients in whom the iris had a normal appearance (p=0.004). The mean superior endothelial cell losses for these two groups was 49% and 21% respectively (p=0.001). The association of superior iris atrophy and excessive endothelial cell loss is likely to reflect an increased degree of difficulty in removal of the nucleus which in turn is related to its density and/or size.

We included diabetics in our study population to permit a comparative analysis of the effects of this technique of cataract surgery on the endothelium of diabetics and non-diabetics. Patients with diabetes have often been excluded from clinical trials that have attempted to assess the deleterious effects of cataract surgery on the corneal endothelium because of the assumption that the diabetic endothelium has an increased susceptibility to damage during surgery. The central and superior mean ECD losses at both 3 and 12 months postoperatively were consistently higher in the diabetic patients; however, the differences did not reach statistical significance. These results are in agreement with the findings of other investigators. Endothelial cell morphology data provide a more sensitive indication of endothelial cell damage than do cell density measurements alone. The COV in cell size and the percentage of hexagonal cells are quantifiable indicators of variation in cell size (polymegathism) and cell shape (pleomorphism). Increases in the COV in cell size and/or decreases in the percentage of hexagons indicate some form of endothelial injury. Analysis of the endothelial cell morphology data demonstrated a similar pattern to the ECD data, with the diabetic group having a larger COV in cell size and a smaller percentage of hexagons without the differences between the groups reaching statistical significance.

Schultz et al. reported that the naturally occurring rate of endothelial cell loss and prevalence of morphological abnormalities in patients with type I diabetes is greater than age matched patients with type II diabetes. The numbers of patients in each of the diabetic subgroups in our study precluded the investigation of the relation between the severity and/or duration of the patients' diabetes and the magnitude of the endothelial cell losses associated with cataract surgery.

What is the clinical significance of endothelial cell losses associated with the use of the ACM which are higher than those reported using other techniques? The average annual endothelial cell loss rate in healthy unoperated eyes is around 0.5%. The chronic exponential endothelial cell loss rate 5–10 years after cataract surgery ranges from 1.1% to 2.5% per annum. While accepting that the endothelial mosaic of the diabetic group has not yet stabilised, it seems reasonable to assume that after the first postoperative year our patients would continue to lose endothelial cells at no more than 2% per annum. As our mean 12 month postoperative ECD was 1965 cells/mm², we can therefore calculate that it would take approximately 50 years before the mean cell density decreased to 500 cells/mm², the level at which corneal decompensation was found to be imminent by Bates et al.
Conclusions and recommendations
The overall results of this clinical trial demonstrate that the efficacy of small incision cataract surgery using the ACM in terms of visual outcome and induced astigmatism is comparable with the results obtained using other techniques that utilise a similar size of incision. The magnitude and range of the endothelial cell losses associated with this technique are, however, significantly greater than those described following phacoemulsification. It has been shown that the use of viscoelastic can reduce the endothelial losses associated with cataract surgery by up to 50%. We would therefore suggest that small incision extracapsular cataract surgery using the ACM is an effective and safe technique, however, in order to minimise endothelial cell losses we would suggest the concurrent use of viscoelastic.

There does not appear to be a statistically or clinically significant difference between non-diabetics and diabetics in the magnitude of the endothelial cell losses or in the wound healing response in the 12 months after cataract surgery using the ACM.
