Should diabetic patients be screened for glaucoma?

John D Ellis, Andrew D Morris, Caroline J MacEwen for the DARTS/MEMO Collaboration

Untreated primary open angle glaucoma (POAG) is a blinding optic neuropathy. Timely medical or surgical treatment is effective in slowing the rate of optic nerve damage and delaying the onset of visually disabling field loss, but treatment is only effective in prevention, and there is as yet no means of reversing established axon loss. In the United Kingdom, around 250,000 people suffer from POAG with visual field loss. The disease accounts for 15% of the 1500 new registrations for blindness in England and Wales per year.8–10

The insidious nature of POAG, its potential detection by relatively simple, non-invasive, screening tests at an early stage, and the existence of treatments effective at preventing disabling visual loss constitute a cogent argument for screening. Consistently, over many years and in numerous different populations, researchers have found that 50% of the disease remains undetected in the community, and one in five of those with newly confirmed disease already have advanced field loss. Clearly, new approaches to the detection of POAG are required if we detect only half the prevalent disease. To target individuals at increased risk would appear to constitute sound clinical and economic practice.8–10

The “Guidelines for the management of ocular hypertension and primary open angle glaucoma” recently published by the Royal College of Ophthalmologists, define risk factors for the development of POAG. These include a positive family history in a first degree relative, high myopia, black race, and diabetes. These groups would therefore appear suitable for targeted screening. The purpose of this review is to examine the evidence that one of these factors, diabetes mellitus, is a risk factor for POAG. It is recommended that all people with diabetes should receive annual screening for diabetic retinopathy, and if there truly is an association between diabetes and POAG, it is tempting to speculate that annual assessment should include a measurement of intraocular pressure (IOP) and that all newly diagnosed glaucoma patients should receive a random blood glucose test.

Related areas of controversy including the protective influence of elevated pressure in the development of diabetic retinopathy2 and the suggestion that diabetic patients may have an excess risk of primary angle closure glaucoma are beyond the scope of this review.

Glaucome and diabetes: is there an association?

The association between diabetes and POAG is not new. In 1971 Becker stated “...diabetes mellitus occurs more often in patients with primary open angle glaucoma than in non-glaucomatous populations. Similarly glaucoma is more prevalent in diabetic than in non-diabetic populations.” This suggested a greater degree of consensus than was warranted at the time, as there was conflicting evidence with some studies reporting an association between diabetes and POAG and others reporting no association. We have performed a critical review of the evidence to clarify the picture.

We reviewed all potentially relevant English language articles from 1966 to 1997 (further papers obtained from bibliography). Inevitably this approach may have introduced bias by the inadvertent omission of non-English language studies. Additionally, there may be other unpublished studies which intuitively are more likely to be negative.

Available studies vary in three principal factors; (i) the population studied—that is, whether patients were selected from the general population or from hospital clinics; (ii) the criteria used to diagnose diabetes; and, (iii) the criteria used to define and diagnose glaucoma.

All studies which have evaluated the association are shown in Table 1. Most of the earlier studies (before 1971) were small, used differing definitions of glaucoma, and were clinic rather than community based and thus examined a selected population. Those that looked at the prevalence of glaucoma, rather than at intraocular pressure only, generally included intraocular pressure as part of the definition of the disease, making it difficult to separate an association of diabetes with ocular hypertension and to exclude low tension glaucoma.

For example, Armstrong et al examined 393 unselected diabetic patients attending a hospital clinic and 280 age and sex matched controls from a general medical clinic, and reported a prevalence of POAG of 4.1% in the diabetic patients compared with 1.4% in the controls. Definite glaucoma was defined as the presence of an IOP >26.5 mm Hg, regardless of field defects. This inevitably included some cases of ocular hypertension. The investigators went on to examine the case records of all subjects who attended the glaucoma clinic (n=325) to ascertain a history of diabetes. This revealed a prevalence of diabetes of 12.6%. However, cases of secondary glaucoma accounted for one third of this group and data on glaucoma type were incomplete. The authors stated that a prevalence of diabetes of 12% is more than would be expected from a normal population thus supporting an association between diabetes and glaucoma. The average age of the patient attending a glaucoma clinic is likely to be high (not stated by the authors) and population prevalence figures for diabetes in white subjects over 65 years of 8–14.7% have been reported. The significance of their findings is therefore uncertain. This study was limited by being clinic based, small, inadequately controlled, and incorporating Stiitz tonometry pressure as the only diagnostic criterion for glaucoma.

In contrast, the Bedford Eye Survey studied 3072 people aged over 40 randomly selected from the general population. Ocular examination included IOP measurement, examination of the optic discs, and Lister perimeter fields. Examination for diabetes included urinalysis and an oral glucose tolerance test (OGTT) in all patients with glycosuria (n=212). The overall prevalence of glaucoma...
was 1.1%. Diabetes was present in 51 patients (1.7%). Although the IOP was greater than 21 mm Hg in two, none of the 51 patients had any of the diagnostic criteria necessary to support a diagnosis of POAG. This study concluded that IOPs in diabetic patients were no different from controls and found no evidence of an association between diabetes and POAG.

In a case-control, questionnaire study Wilson et al.19 studied 83 confirmed and 121 possible glaucoma cases (total 204) selected from a hospital clinic. Control patients (237) were from the same ophthalmic clinics in whom a diagnosis of glaucoma had been excluded. A questionnaire established history of drug exposure, race, family history, and smoking habits. Diabetes, hypertension, and myopia were defined by interview. All variables were analysed by a multivariate regression model to define risk factors for POAG. A case of glaucoma was defined as IOP >21 mm Hg if associated with large or asymmetric disc cupping. There were no requirements for a diagnostic field change. Cases were also defined as glaucomatous if IOP >30 mm Hg in both eyes regardless of disc appearance, thus inevitably misclassifying some cases of ocular hypertension. The ascertainment of glaucoma was weakly associated with diabetes (adjusted rate ratio 1.6). The number of patients with diabetes was small (10 cases, 16 controls), however, which limited the power of the study and the significance of the observed association with diabetes.

These early studies contribute little meaningful information principally because of limitations in study design. More recently, four population based studies have been published which merit detailed discussion.

Recent studies

All subjects in the Framingham Study30 were screened for POAG by application tonometry and funduscopy. Subjects with elevated IOP or suspicious discs underwent Goldmann perimetry. There were 2315 subjects with complete data; and diabetic status was defined as part of the Framingham Heart Study. There was a direct relation between blood glucose and IOP (15.3% of diabetic patients had an IOP >21 mm Hg in at least one eye compared with 9.8% in at least one eye for the group as a whole—adjusted odds ratio 2.3), but not between diabetes and a clinical diagnosis of POAG. There were 54 confirmed cases of POAG (prevalence 2%). In a second report from the same group they examined cardiovascular risk variables and visual field defects, diabetes was increased twofold in those with IOP >21 mm Hg. In this study visual field defects did not correlate with diabetes.

A sample of 2990 diabetic patients (1210 type 1 diabetes, 1780 type 2 diabetes) and 381 controls from the community based validated group of diabetic patients (n=10 135) in the Wisconsin Study of Diabetic Retinopathy32 were examined with Goldmann applanation tonometry. There were 2315 subjects with complete data; and diabetic status was defined either by a history of previously diagnosed and treated diabetes (n=395) or by a glycosylated haemoglobin greater than two standard deviations above the age matched mean or a random blood glucose greater than 11.1 mmol/l (n=50). The study found a twofold increase of both definite and probable glaucoma in diabetic subjects (33 of 426 combined) compared with non-diabetic subjects (172 of 4420). They also found twice as many subjects had IOP >21 mm Hg in at least one eye among diabetic patients as among non-diabetics.
The Baltimore Eye Survey\textsuperscript{34} examined 5308 subjects aged over 40 for a diagnosis of glaucoma. Ocular examination included applanation tonometry, stereo fundus photography of the discs and Humphrey automated or Goldmann perimetry. The diagnosis of POAG required open angles, disc cupping, and rim thinning with characteristic field changes required to match disc rim thinning in the absence of any other pathology. Elevation of IOP was not necessary for a diagnosis of glaucoma. A second ophthalmologist independently reviewed all cases.

In contrast with the rigorous definition of POAG, the presence of diabetes was defined by a positive response to a question about treatment for, or a history of, diabetes diagnosed in the past. A prevalence of diabetes of 10.6\% among whites and 17.2\% among blacks was found. The authors comment, reasonably, that differential reporting of diabetes between subjects with and without glaucoma is unlikely. Non-differential misclassification, however, will usually bias estimates of the odds ratio towards the null value and may mask any true effect.\textsuperscript{35} The study found no association between diabetes and POAG (odds ratio 1.03) in those examined and diagnosed as having glaucoma for the first time, but patients with a prior diagnosis of POAG showed a positive association with diabetes (odds ratio 1.7) again suggesting that referral bias may be responsible for some of the positive associations reported in previous clinic based studies. It is interesting that this figure is almost identical to that found in the clinic based study by Wilson et al.\textsuperscript{29}

Finally in the Rotterdam Study,\textsuperscript{36} 4012 subjects aged 55 or over received full ocular examination for glaucoma, and a non-fasting oral glucose tolerance test for diabetes. Diabetic patients on antidiabetic medication were not given an OGTT and were therefore excluded. Glaucoma was defined by Goldmann applanation tonometry, Humphrey automated fields, and disc photography after instillation of a mydriatic. A visual field defect (carefully defined in the article) matching discs and classic for glaucoma was required for the diagnosis. Gonioscopy was performed on all patients with glaucomatous field defects. The study identified 37 patients with POAG (no other forms of glaucoma were identified) and for over half of these (53\%) the diagnosis was new. The authors reported a threefold increase in the presence of high tension glaucoma (crude odds ratio 4.18; age, sex, and hypertension adjusted OR 3.11) in people with diabetes and a diabetic OGTT. The numbers with normal tension glaucoma were too small for separate statistical analysis.

**Interpretation of existing studies**

Overall interpretation of the data from the above studies is fraught with difficulty. The definition of glaucoma differed too widely to allow meaningful comparison between early studies, and discrepancies in population and diabetes definition make comparison between most of the later studies similarly problematic.

Despite the relative ease with which patients with diabetes and POAG can be recruited from clinic populations, data from clinic based studies must be viewed with caution because both diabetes and POAG are under-diagnosed conditions and selection bias is therefore inevitable.

Studies based on screening of the general population have attempted to overcome this problem. The definition of diabetes by questionnaire rather than examination may introduce error because of recall bias and underestimate prevalence because of the large subclinical component of the disease. Studies that have based their findings on special screening programmes which have included biochemical confirmation of diabetes are to some extent limited by the fact that the number of patients with POAG detected by mass screening are relatively small.\textsuperscript{8, 11, 15, 16, 18} Nevertheless, because the prevalence of diabetes in these populations (aged over 40) in developed countries is much higher than the average for the population as a whole,\textsuperscript{27, 38} these studies may be adequately powered to detect an association, although this is not always the case.\textsuperscript{29}

In addition to the above discussion, it should be stated that some studies have potentially underestimated glaucoma incidence because they have concentrated on people with type 1 diabetes too young to have an appreciable risk of developing POAG.\textsuperscript{10}

All the above studies are prevalence based case-control studies—we found no published incidence based studies. In general, case-control studies are subject to survival bias, misclassification, and recall bias. Studies based on totally unresolved populations minimise selection bias and are the only way of gaining reliable information about chronic, insidious, largely underdiagnosed conditions such as POAG and diabetes. If the population is too small, however, this can introduce bias of its own. In light of recent advances in the genetic epidemiology of POAG the possibility of founder effects in geographically defined populations has to be considered: the generalisability of such findings is still not assured.

Total population studies in defined areas have been achieved in Wales (91.9\% of population covered)\textsuperscript{39} and Sweden\textsuperscript{40} but neither study looked at the incidence of, or relation to, diabetes. In the same year, the authors commented reasonably that diabetics and POAG were so rare that they could be considered worthwhile.

**Conclusion**

Screening all diabetic patients for POAG at the time of annual screening for retinopathy is an attractive proposition provided a clear clinical benefit could be demonstrated.\textsuperscript{31} A screening test should ideally be relatively inexpensive, simple, and quick to perform and if possible be capable of being administered by a non-specialist. IOP testing by Tonopen would meet these criteria but would be too imprecise as a sole screening test. Further limiting the value of tonometry in this context are those studies which have suggested elevation of IOP in diabetes independent of POAG risk.\textsuperscript{14, 16, 31, 34, 42} Field testing would increase specificity but is technically demanding for the patient, expensive and, as a sole means of detecting glaucoma Klein and colleagues found, had a positive predictive power of only 16\%.\textsuperscript{43} It is readily apparent that clear evidence that diabetic patients are indeed at significant risk of POAG is needed before screening can be considered worthwhile.

Meta-analysis of available data is impossible and accordingly it is not yet possible to define the attributable risk of glaucoma due to diabetes. Our current knowledge is insufficient to state with conviction that diabetes is a risk factor for the development of POAG. This is not to say that such a risk does not exist; only that conclusive evidence for it does not. To the best of our knowledge, only two adequately performed studies have borne out an association between the two diseases.\textsuperscript{15, 16} and one equally well
conducted study (the largest in the world literature) has failed to confirm any association apart from that explained by referral bias.

Further information from a prospective, general population based, incidence study of all subjects in a community with full ascertainment of diabetes would be helpful. This presents its own difficulties. Studies which have defined the prevalence of diabetes in an entire population have yielded inconsistent prevalence rates principally because of the difficulty in full ascertainment of type 2 diabetes, in particular diet controlled diabetes. The most accurate UK data from Tayside, Scotland, indicate that the prevalence of diabetes is 1.94%, but increases to 5.3% in those aged >55 years who are at greatest risk of POAG. If at least 5.3% of the population aged >55 years are diabetic and the ratio of diagnosed to undiagnosed POAG is assumed to be 50:50, based on 1996 census data there may be as many as 12,000 diabetic patients with undiagnosed POAG in the United Kingdom if diabetic patients are not at excess risk of developing the disease. If, however, diabetic patients are at increased risk of developing POAG applying the lowest and highest odds ratios quoted in the literature (1.03 and 3.11 respectively) would mean a further 300 to 3120 patients may have undiagnosed POAG.

The above calculation assumes that the ratio of diagnosed to undiagnosed disease matches that of the general population. This is almost certainly not the case. Increased contact with community and hospital based ophthalmic services is likely to alter this ratio significantly, and may in fact more than compensate for any increased risk. The recent Royal College of Ophthalmologists recommendations state that diabetic patients are at increased risk of POAG: based on our review of the world literature we believe that there is too much conflicting evidence to extrapolate that screening be recommended for a subgroup of diabetic patients whose exact size, and even possible existence, remains in doubt.
