Diagnosis of viral and chlamydial keratoconjunctivitis: which laboratory test?

Elfath M Elnifro, Robert J Cooper, Paul E Klapper, Andrew S Bailey, Andrew B Tullo

Conjunctivitis and keratitis are common forms of ocular morbidity seen in general practice and eye units. The aetiology of these diseases includes viral, bacterial, or parasitic infection as well as allergy, trauma, and dietary deficiency. Among the common microbial causes are adenovirus, herpes simplex virus (HSV), and Chlamydia trachomatis. Ocular adenovirus infections occur throughout the world in both sporadic and epidemic forms, and large scale outbreaks of epidemic keratoconjunctivitis can occur in hospitals, schools, military establishments, or factories. HSV type 1 ocular infection occurs in all countries with an annual incidence of up to 20.7 per 100,000 population and is the most common infectious cause of blindness in developed countries.49 Traumatic keratitis is one of the leading infectious causes of blindness in the world and is a major public health problem in developing countries.10 Adult chlamydial conjunctivitis, caused by C. trachomatis serovars D–K, is an ocu
genital infection and up to 90% of patients have concurrent genital infection.11–13 Chlamydial neonatal conjunctivitis (ophthalmia neonatorum) develops in 18%–74% of babies born to mothers with genital chlamydial infection.7

This article reviews available diagnostic laboratory techniques for keratoconjunctivitis caused by adenovirus, HSV, and C. trachomatis with special emphasis on modern molecular diagnostic techniques. For information on the clinical features, epidemiology, and treatment of these infections the reader is referred to a number of other reviews.8 9 14–17

### The need for laboratory investigation

Owing to the limited reliability of clinical diagnosis of adenovirus, HSV, and C. trachomatis induced keratoconjunctivitis,16–25 accurate laboratory investigation for these agents in conjunctival swabs is often valuable. Failure to diagnose ocular adenoviral disease can result in outbreaks of epidemic keratoconjunctivitis. Prompt recognition of the strains of adenovirus causing this condition in patients can, however, help to contain the development of a hospital based epidemic.24 C. trachomatis infection (particularly with serovars D–K) is usually associated with asymptomatic genitourinary colonisation.25 Misdiagnosis of this ocular infection may represent a missed opportunity to detect infection of the genital tract which can ultimately result in a series of complications including pelvic inflammatory disease, epididymitis, ectopic pregnancy, and infertility in the patient and/or partner.10,13,25 In addition, delay in diagnosing chlamydial conjunctivitis and the use of inappropriate antibiotic treatment might trigger chlamydial persistence.26 The availability of appropriate treatment for chlamydia,27 HSV,11 and possibly adenovirus23 together with the potentially serious residual morbidity of these infections clearly justifies the need for accurate laboratory investigation in cases of keratoconjunctivitis.

### Conventional laboratory techniques

The conventional techniques for diagnosing viral and chlamydial keratoconjunctivitis include conjunctival cytological investigation28–30; inoculation of susceptible cell lines followed by observation of cytopathic effect or visualisation

using various chemical or immunological staining techniques; examination of blood and/or tears for various classes of antibodies; and detection of viral or chlamydial antigens in conjunctival and corneal specimens. Nevertheless, the pitfalls of these conventional techniques are numerous. Traditional cytological investigation is insensitive and subjective. Nevertheless, owing to its speed and sensitivity, PCR is a useful diagnostic tool for HSV infection of the ocular surface. In our own laboratory, the overall sensitivity of PCR for detection of adenovirus in eye swabs was similar to that of cell culture and superior to that of antigen detection by immune dot-blot test. More recently, using a newly designed adenovirus primer pair, we have a PCR which is significantly more sensitive than culture. Of 415 eye swabs positive by culture and/or PCR, 386 (93%) were positive by PCR compared with 248 (59%) by cell culture.

Polymerase chain reaction (PCR)

PCR allows the identification of extremely small quantities of DNA with a very high degree of specificity. The test has revolutionised the diagnosis of microbial diseases and, in its first use in eye disease in 1990, the test is now being widely used in clinical ophthalmology. Owing to its speed over tissue culture isolation and in sensitivity over immunoassay (Adenoclone). The PCR was positive in 46 of 58 adenoclone negative, culture positive swabs, and in 11 of 11 adenoclone positive, culture positive swabs. Only one of 38 non-adenoviral ocular swab samples was positive by PCR giving an overall specificity of 97.3%. These results demonstrate the superiority of PCR in terms of speed over tissue culture isolation and in sensitivity over immunoassay.

In our own laboratory, the overall sensitivity of PCR for detection of adenovirus in eye swabs was similar to that of cell culture and superior to that of antigen detection by immune dot-blot test. More recently, using a newly designed adenovirus primer pair, we have a PCR which is significantly more sensitive than culture. Of 415 eye swabs positive by culture and/or PCR, 386 (93%) were positive by PCR compared with 248 (59%) by cell culture.

ADENOVIRUS

PCR may be the only means by which rapid and reliable diagnosis of adenoviral keratoconjunctivitis can be achieved. The technique has been shown to be more sensitive, accurate, and rapid than culture for detecting and typing adenovirus in cases of conjunctivitis. In addition, PCR appears to be more sensitive than immunoassay in detection of ocular adenovirus infections. For example, Chinkinson et al evaluated the application of PCR in 107 ocular swab samples and correlated the results with those obtained with tissue culture and a commercial immunoassay (Adenoclone). The PCR was positive in 46 of 58 adenoclone negative, culture positive swabs, and in 11 of 11 adenoclone positive, culture positive swabs. Only one of 38 non-adenoviral ocular swab samples was positive by PCR giving an overall specificity of 97.3%. These results demonstrate the superiority of PCR in terms of speed over tissue culture isolation and in sensitivity over immunoassay.

In our own laboratory, the overall sensitivity of PCR for detection of adenovirus in eye swabs was similar to that of cell culture and superior to that of antigen detection by immune dot-blot test. More recently, using a newly designed adenovirus primer pair, we have a PCR which is significantly more sensitive than culture. Of 415 eye swabs positive by culture and/or PCR, 386 (93%) were positive by PCR compared with 248 (59%) by cell culture.

HERPES SIMPLEX VIRUS

Few studies have compared PCR with conventional techniques. This is probably because the clinical features of herpetic eye disease are often strongly suggestive and culture results are available much sooner (3 days) than those of adenovirus (up to 4 weeks) and chlamydia (5 days). Nevertheless, owing to its speed and sensitivity, PCR is a useful diagnostic tool for HSV infection of the ocular surface. Yamamoto et al utilised PCR for the detection of HSV genomic sequences in tear film from patients with clinically diagnosed HSV keratitis. The PCR was positive in 12 of 12 epithelial keratitis specimens, two of six stromal keratitis, but in none of 20 normal specimens. In another study by Kowalski et al utilising cell culture as a gold standard test, PCR was shown to be
significantly more sensitive (95%) in diagnosing herpetic ocular disease than diagnosis by clinical examination (55%).

CHLAMYDIA TRACHOMATIS

For *C. trachomatis*, the PCR has been shown to be as or more sensitive than conventional techniques. Bobo et al. investigated the use of PCR in 234 Tanzanian children who were clinically classified as having no sign of trachoma (n=97), follicular trachoma (n=100), or intense inflammatory trachoma (n=37). The PCR detected *C. trachomatis* in 24%, 54%, and 95% of subjects, respectively, compared with detection by direct immunofluorescence of 1%, 28%, and 60%, respectively. The overall prevalence of chlamydial eye infection was 48% by PCR compared with 22% by direct immunofluorescence. In addition, this study showed the utility of PCR as a suitable method for field use owing to ease of specimen collection and transport.

In the United States, Talley et al. screened ocular swabs from 30 consecutive patients with follicular conjunctivitis for adenovirus, HSV, and *C. trachomatis*. In this study, PCR was compared with cell culture and direct immunofluorescence for the detection of *C. trachomatis*. Only four patients were positive for *C. trachomatis* by PCR. Two of the four patients were positive by cell culture and one of four patients was positive by direct immunofluorescence. Thus, PCR appeared to be an equally specific and more sensitive method than cell culture or the direct immunofluorescence test. In another study Tabrizi et al. compared culture and PCR techniques in the detection of *C. trachomatis* in 200 clinical samples including eye swabs (30%). A total of 173 specimens were assessable by PCR of which 24 (13.8%) were positive by both methods and four specimens were positive by PCR and negative by culture. Overall the PCR was 100% sensitive and 97.3% specific compared with cell culture. Taller et al. evaluated the use of PCR, direct immunofluorescence, and serology for the detection of chlamydial IgA and IgG in 93 patients with follicular conjunctivitis. In comparison with cell culture, the sensitivities of PCR, direct immunofluorescence, and the three assays for IgA or IgG were 100%, 83.3%, and 62.5%–75% or 37.5%–100%, respectively, with specificities of 100%, 96.6%, and 70.6%–81% or 47.3%–64.8%, respectively. In a study of 75 cases of neonatal conjunctivitis, a commercially available PCR assay, Roche Amplicor, was found to be equivalent to culture for conjunctival specimens with sensitivity, specificity, and positive and negative predictive values of 92.3, 100, 100, and 98.4%, respectively. PCR is a valuable epidemiological tool for detecting and genotyping ocular strains of *C. trachomatis* from cases of inclusion conjunctivitis and trachoma.

RELIABILITY

Because of its sensitivity, false positive results due to the carryover of small amounts of the products of previous PCR tests may be encountered. Such problems can be avoided by strict application of a variety of preventative measures. False negative results may arise as a result of failure of PCR amplification. The most common cause of PCR failure is due to the introduction of inhibitors with the test sample. A variety of sample preparation techniques are now available to help avoid such problems and control for sample inhibition can be accomplished by the inclusion of internal control molecules or by amplification of human DNA in the sample (for example, β-globin gene).

AUTOMATION

Nucleic acid amplification procedures may be automated to improve the reproducibility, speed, and overall cost of tests. An example is the Cobas Amplicor (Roche Molecular Systems) automated PCR system and the ligase chain reaction test kit (Abbott Diagnostics Ltd). While commercial test procedures and automation are, in relation to ocular disease, currently only available for *C. trachomatis*, the available test repertoire is increasing. The more widespread application of these tests is anticipated, particularly as they overcome the problem of variable sensitivity and specificity between laboratories using their own “in house” procedures.

Discussion and conclusions

The ideal test for diagnosing ocular pathogens has been defined as one whose result is available before the patient leaves the doctor’s office. However, achieving sensitivity, specificity, low cost, long term shelf storage, and ease of performance by office staff without the need for expensive equipment or hazardous reagents currently presents a formidable technological challenge. Although PCR achieves the accuracy needed for diagnosis of ocular infectious agents, it still lacks the speed and simplicity required for an office based test. The anticipated introduction of effective treatment of adenoviral keratoconjunctivitis poses a real challenge to the applicability of the emerging tests discussed in this review. To allow dispensing of treatment and discharge of the patient from clinic (where cases of adenoviral keratoconjunctivitis pose a real threat to other patients and staff) test results would be required within 10–30 minutes. At the present time only immunochromatography can provide information within such a time frame but the low sensitivity of such tests is a major drawback.

The choice of the optimal technique for diagnosing viral and chlamydial keratoconjunctivitis depends upon the efficiency, speed, and cost of the test. The performance of conventional laboratory procedures is relatively poor and the interpretative difficulties documented with these tests are well recognized. Owing to their inherent sensitivity and high specificity, nucleic acid amplification procedures, in particular PCR, are recognized as the ultimate modern diagnostic tool for the identification of adenovirus, HSV, and C trachomatis in clinical eye swab samples. However, in laboratories without access to PCR, the conventional techniques of enzyme immunoassay, culture, and direct immunofluorescence are useful for diagnosing adenovirus, HSV, and chlamydia. The direct immunofluorescence test can, however, only be recommended if a small number of specimens are submitted and examined by skilled and experienced microscopists and although commercial enzyme immunoassays have the advantages of low cost and suitability for testing large numbers of specimens, the false positive and false negative results generated are serious disadvantages. Particularly in relation to C trachomatis infection, inaccurate diagnosis in a patient being investigated for conjunctivitis and not sexually transmitted disease, can lead to difficult communication with the patient and even litigation.

A conceptual difficulty with all nucleic acid amplification procedures is the finding of positive detection of nucleic acid in the absence of viable organisms (as determined by culture) or of antigen (immunoassay). The current sophistication of PCR means that provided due attention is given to intralaboratory quality control including rigorous application of anti-cross contamination procedures, the finding of the nucleic acid of an organism in an ocular specimen is significant. The presence of residual nucleic acid usually indicates that infection persists well beyond the period indicated by cell culture or antigen detection tests. Factors generated in the course of the clinical response such as the elaboration of antibodies, interleukin 1, interferon gamma, and tumour necrosis factor (TNF) might inhibit or alter the metabolic capacity, surface receptor expression, or infectivity and therefore culturability or the antigenicity of the organism. In this way the infectivity might fall while the organism, containing DNA, is still detectable by PCR.

Nucleic acid amplification may, as has happened with other non-culture diagnostic procedures, also detect an infectious agent in circumstances which are not consistent with the clinical features under investigation. Such findings should not be dismissed because these diagnostic procedures have proved to be a powerful tool in elucidating the aetiology of several ocular diseases previously classified as idiopathic.

A further item of value in detection of nucleic acid in ocular specimens is in the assessment of treatment failure. Until recently, treatment failure was defined solely on the basis of positive culture. For the reasons outlined above, the lack of detection of infectious organisms may not signal the end of a disease process. Non-culture test results, particularly those of high sensitivity, are very probably a more reliable indicator of treatment failure. The continued development of nucleic acid amplification procedures will lead to the wider availability of quantitative procedures which will refine our ability to monitor the efficiency and progress of therapeutic regimens.

The continued development of nucleic acid amplification procedures will also lead to a reduction in the overall cost of diagnosing viral and chlamydial keratoconjunctivitis. Already PCR procedures are available to allow the simultaneous investigation of several pathogens using one test in which the three or more organism specific oligonucleotide primer pairs are included (multiplex PCR). Such tests allow the testing of a single sample and permit easy identification of possible, albeit rare, concurrent infection.106–107 In our own laboratory, for example, a multiplex PCR has been developed for the simultaneous investigation of adenosivirus, HSV, and β globin in ocular swabs and, currently, we are modifying the technique to include C trachomatis detection.

In conclusion, nucleic acid amplification procedures are valuable modern techniques for the diagnosis of infectious ocular disease. The availability of automation and the more widespread availability of commercial assays will facilitate the use of these techniques in routine laboratories. These techniques are evolving rapidly and are likely to have an increasingly important role in therapeutic management.
