Prophylactic scleral buckle for prevention of retinal detachment following vitrectomy for macular hole

EDITOR,—Chang et al

postoperative peripheral visual fields compared with those of the fellow eye have resulted in a final visual acuity significantly lower than in eyes without such complication,2 even if surgery to reattach the retina is successful. Prophylaxis of retinal detachment is therefore of great importance.

Certain precautions such as careful peeling of the still attached posterior hyaloid face and careful inspection of the retinal periphery with scleral indentation before fluid-air exchange are useful in reducing the rate of postoperative retinal detachment. Having been alerted to the unexpected frequency of this complication, however, such precautions are already observed by most surgeons performing macular hole repair. Additional preventive measures are warranted for those continuing to experience retinal detachment despite careful techniques.

Since scleral buckling has been found by some authors to reduce the incidence of retinal detachment in trauma,1 while others have not identified it as effective or necessary,3 an encircling band is useful in reducing traction at the vitreous base,1 but perhaps less effective in preventing retinal detachment in the presence of a retinal break created by a partial vitreous detachment as in case of macular hole surgery. Indeed, the authors’ incidence of retinal detachment in eyes despite placing a prophylactic buckle was still 5.9%, a figure most surgeons would consider rather high. In addition, an encircling band has certain morbidity that cannot be ignored.

In 1995 we have elected to reduce the incidence of retinal detachment in our macular hole surgeries using a different strategy. Following fluid-air exchange, we perform indirect ophthalmoscopic (IDO) laser cerclage in a moderately tight PRP pattern (800–1200 spots) from the ora serrata to the equator, sparing the horizontal meridians. The postoperative peripheral visual fields compared with the those of the fellow eye have not been significantly reduced, and no complication of IDO laser retinopexy was seen in over 200 eyes. We have followed 94 consecutive eyes for over 6 months after surgery with no case of retinal detachment. This contrasts with our other series in which the surgical technique was identical except that no laser cerclage was performed. In this series of 47 consecutive cases, eye (7%) developed retinal detachment (Mester and Kuhn, submitted for publication).

EDITOR,—We would like to thank Morris et al for bringing to light some of the important issues regarding macular hole surgery that we discussed in our article. One of the fundamental points that remain to be considered in this subject is a determination of the actual retinal detachment rate for this procedure. In a multicentred randomised clinical trial for macular hole surgery the retinal detachment rate was noted to be as high as 14%.5 Several retrospective series have noted a considerably lower rate although this may reflect a “reporting bias”. That is to say, retrospective series with lower than expected success rates or higher than expected complication rate often are not submitted for publication review.

If we assume that the detachment rate may be higher for patients undergoing macular hole surgery, it then behoves us to identify methods of lowering this incidence. Morris and colleagues have described a novel technique of prophylactic laser cerclage that likely would have lower ocular morbidity. Prospective evaluation of this and other methods would be helpful in investigating the optimum approach to this problem.

Membrane formation in the chamber angle after failure of argon laser trabeculoplasty

EDITOR,—I read with interest the article by Koller and co-workers,1 in which the authors investigated causes and risk factors for membrane formation in the anterior chamber after argon laser trabeculoplasty (ALT). In their discussion the authors conclude that ALT and especially repeated ALT represent a risk for late membrane formation over the trabecular meshwork, which leads to late failure of ALT. They suggest that both repeated ALT and immediate intraocular pressure (IOP) spikes after ALT are induced by the same mechanism—that is, laser induced inflammation.

I agree with the authors that laser induced inflammation is a possible factor for subacute and late membrane formation over the trabecular meshwork. In a retrospective study2 in which the duration of success (IOP <22 mm Hg after treatment) was investigated we found that the length of success was significantly shorter in eyes which received no topical anti-inflammatory medication after ALT compared with the eyes which received such a treatment for 5 days following the same procedure. Is the risk for membrane formation similar after laser trabeculoplasties using different lasers? The authors did not discuss this question; however, this is a point of practical importance. In a prospective, comparative clinical and morphological study3 one randomly selected eye of the patients underwent a conventional ALT, and the contralateral eye received a similar treatment but with a very low energy level of a pulsed Nd:YAG laser. In this study, which I performed several years before selective laser trabeculoplasty was developed, both eyes of the participants had identical type of open angle glaucoma in a

very similar stage before treatment. The clinical efficacy of both types of trabeculectomy was similar. The most important difference found in the eyes requiring trabeculectomy was the presence of a membrane over the trabecular meshwork after ALT and the absence of this membrane after Nd:YAG laser trabeculoplasty in the same patients. These findings suggest that the type of laser or its thermal effect are also important factors when the causes of late failure are discussed.

In contrast with the authors' opinion I do not think that immediate IOP spikes 1 or 2 hours after ALT are caused by prostaglandins of different origin. In clinical studies it was clearly shown that either topical corticosteroid or non-steroid pretreatments failed to reduce the early IOP spike though both types of treatments did reduce the inflammation after ALT. This clearly shows that late and long-term IOP elevations are caused by different mechanisms. Recently it was shown that the trabecular meshwork contains contractile elements which are contracted by endothelin-1 (ET-1). The contraction causes a decrease of the outflow and a resulting IOP elevation. Lower ET-1 concentration, however, may induce relaxation via endothelin B receptors. In experimental studies exogenous ET-1 injected into the anterior chamber caused the typical biphasic IOP alterations we experience after ALT in clinical praxis: an immediate spike is followed by a prolonged (10–15 days) pressure decrease. Long-term IOP decrease on the treated but not on the sham treated eyes of the same animals. These findings are consistent with the latest information please contact Community Eye Health, International Centre for Eye Health, Institute of Ophthalmology, 11–43 Bath Street, London EC1V 9EL.
