Bilateral cavernous haemangiomas of the orbit

EDITOR,—The great majority of orbital tumours are unilateral. However, some conditions, such as idiopathic orbital inflammation (“pseudotumour”), granulomatous inflammation, lymphoid tumours, or metastases sometimes can be bilateral. Orbital cavernous haemangioma is almost always unilateral.1,2 We report a patient with bilateral orbital cavernous haemangiomas that caused unilateral proptosis and visual distortion.

CASE REPORT
A 37 year old man developed distorted vision in the inferior field of his left eye and was found to have mild left proptosis. There was mild swelling of the left optic disc and a small inferonasal visual field defect. Orbital computed tomography (CT) revealed bilateral orbital masses and the patient was referred to the oncology service for another opinion and management. His visual acuity was 6/6 in each eye and colour vision was normal in both eyes. The only positive findings were 3 mm of left eye and colour vision was normal in both eyes.

COMMENT
Cavernous haemangioma of the orbit is a common, benign tumour that almost always occurs unilaterally. There are rare reports of bilateral orbital cavernous haemangiomas. Fries and Char reported a case that was very similar to ours.3 They excised the tumour in one orbit and elected to follow the asymptomatic tumour in the opposite orbit. Sullivan and associates reported an unusual case of multiple bilateral orbital haemangiomas.4 Johnson and co-workers reported bilateral orbital haemangiomas as part of Maffucci’s syndrome, a condition characterised by enchondromatosis and multiple systemic haemangiomas.5 Our patient was otherwise normal with no evidence of Maffucci’s syndrome. There was also a recent report of bilateral orbital vascular masses, presumed orbital varices, that caused intravascular papillary endothelial hyperplasia.6

The widespread use of CT and magnetic resonance imaging to evaluate unrelated problems, such as headache, has led to the recognition of asymptomatic lesions compatible with orbital cavernous haemangioma. We have seen several such cases and have elected to follow without treatment these small, asymptomatic tumours, presumed to be bilateral cavernous haemangiomas. Consequently, it is possible that orbital cavernous haemangioma may be more common than previously believed. If so, additional cases of bilateral orbital cavernous haemangioma will probably be recognised. In our case, the asymptomatic tumour in the right orbit most likely is a cavernous haemangioma, but periodic observation, rather than surgical excision, would seem to be the best management. In summary, the opthalmologist should include orbital cavernous haemangioma in the differential diagnosis of bilateral, as well as unilateral, orbital tumours.

Choroidal neovascularisation at a demarcation line: an immunopathological study

EDITOR.—We describe a patient presenting with a choroidal neovascular membrane (CNVM) at the demarcation line of a longstanding rhegmatogenous retinal detachment (RRD), and characterise its immunopathological features following surgical removal.

CASE REPORT
A 46 year old myopic woman attended the vitreoretinal service with a 3 month history of a shadow in the superior half of her left visual field. Her visual acuity was 6/9 right and 6/12 left, with a refractive error of −13.0D and −9.50D effective spheres respectively.

Examination of the left fundus revealed longstanding detached and thinned retina inferioirly and a broad heavily pigmented demarcation line passing through the macula with associated retinal pigment epithelial (RPE) hyperthrophy. An area of paravascular retina adjacent to the tide mark appeared elevated and a fundus fluorescein angiogram

Choroidal neovascularisation at a demarcation line: an immunopathological study

EDITOR.—We describe a patient presenting with a choroidal neovascular membrane (CNVM) at the demarcation line of a longstanding rhegmatogenous retinal detachment (RRD), and characterise its immunopathological features following surgical removal.

CASE REPORT
A 46 year old myopic woman attended the vitreoretinal service with a 3 month history of a shadow in the superior half of her left visual field. Her visual acuity was 6/9 right and 6/12 left, with a refractive error of −13.0D and −9.50D effective spheres respectively.
(FOA) revealed a juxtafoveal CNVM emerging from the edge of RPE hypertrophy. Three months later she reported decreased vision and metamorphopsia in her left eye, with a best corrected left visual acuity reduced to counting fingers. A subfoveal extension of the CNVM with bordering haemorrhage was present, confirmed by FFA (Fig 1A, B). She subsequently underwent pars plana vitrectomy, parafoveal retinotomy, and removal of subfoveal CNVM, together with external scleral buckling, argon laser retinopexy, and 20% sulphur hexafluoride gas tamponade.

Postoperatively, an area of inferior retinal detachment persisted and further surgery with silicone oil tamponade was undertaken. Subsequently, a posterior subcapsular cataract developed and she underwent left phacoemulsification with intraocular lens implantation and removal of silicone oil. Postoperatively, visual acuity improved to 6/18 and the retina remained flat with no clinically apparent CNVM (Fig 1C). Four months later, her visual acuity was reduced to 6/36. Fundal examination showed an elevated area at her fovea and FFA confirmed a recurrent CNVM. We are treating this conservatively as the patient is asymptomatic and has declined further surgery.

**PATHOLOGY**

The CNVM specimen was fixed in 10% formal saline, processed through ascending concentrations of alcohol into xylene and embedded with paraffin wax. Tissue sections 5 μm thick were freshly cut for this study, dehydrated, and rehydrated before use.

The distribution of basic fibroblast growth factor (bFGF), vascular endothelial growth factor (VEGF), macrophages (PGM1), and von Willebrand factor (vWF) were investigated using a standard biotin-streptavidin-biotin, alkaline phosphatase complex method (Dako Ltd). The alkaline phosphatase label was visualised as a red final reaction product (Vector Ltd). Nuclei were weakly stained with Mayer’s haematoxylin. A normal human donor eye was used as a positive control, while the negative control used was normal rabbit serum diluted to give a final protein concentration equivalent to that of the primary antibody used.

Histopathological examination revealed a CNVM consisting of numerous endothelial lined vascular channels and chronic inflammatory cells. The CNVM was lined by an incomplete layer of RPE cells on its posterior aspect, as determined by the clinical orientation of the membrane at the time of removal (Fig 2A).

A large portion of the CNVM consisted of vascular channels lined by endothelial cells displaying immunoreactivity for von Willebrand antigens (Fig 2B). There was staining for VEGF (Fig 2C) and bFGF (Fig 2D) in the extracellular matrix, with a similar distribution of immunoreactivity.

**COMMENT**

Choroidal neovascularisation occurs in a wide spectrum of conditions, including degenerative, inflammatory, traumatic, and hereditary disorders—all characterised by breaks in Bruch’s membrane. A few cases of CNVM developing at the edge of a demarcation line have been reported in both chronic rhegmatogenous and tractional retinal detachments; however, the immunopathology does not appear to have been previously described.

A demarcation line (“high watermark”) is characteristically found in longstanding retinal detachments that either progress very slowly or remain static. In this setting, RPE cells may detach from Bruch’s membrane to proliferate and undergo metaplasia in the subretinal space at the junction of attached and detached retina. Clinically, a demarcation line appears as a line of increased pigmentation in this area and may form a sufficiently firm adhesion to prevent progression of a retinal detachment. The local wound healing response at the edge of the detached retina may also lead to excessive RPE proliferation. In our patient, such chorioretinal adhesion may have allowed the transmission of mechanical vitreo-retinal traction forces to Bruch’s membrane.

This could potentially have compromised the integrity of Bruch’s membrane, allowing the formation of a CNVM. High myopia was a further predisposing factor for choroidal neovascularisation in this patient, making Bruch’s membrane more susceptible to disruption.

Grossniklaus and Gass have described two fundamentally different types of choroidal neovascular growth patterns—type 1, with growth of new vessels beneath the retinal pigment epithelium, and type 2, with growth of new vessels in the subsensory retinal space.

In our patient, the presence of RPE cells on the posterior surface of the CNVM indicates that it represented a type 2 membrane, as determined by its clinical orientation at the time of removal.

Experimentally detached retina in cats has been shown to possess higher angiogenic activity than normal attached retina. Indeed, peripheral retinal neovascularisation has been described in chronic rhegmatogenous retinal detachment. Retinal detachment is likely to lead to compromised metabolism and hypoxia of the outer retinal layers due to elevation of the retina from the choroid. RPE cells may...
A 42 year old white man presented with a his-

tory of a small superficial black mark in the

lower back. On histopathology, this had been

diagnosed as a superficial spreading type

lesion. The patient was counselled and referred to the oncologist

during his presentation.

CASE REPORT

A 42 year old white man presented with a his-
tory of a small superficial black mark in the

temporal aspect of the right eye, which had

infiltrate seen at the edges. It had been excised

completely with no vascular or lymphatic

infiltration seen in the section. He had been

thoroughly screened and a computed tomo-

gram (CT) scan of the abdomen and head

had revealed no metastases. Subse-
dently, he had been followed up on a 4

monthly basis over the next 2 years and no

recurrences had been found. During this

period he developed a severe form of asthma

which was controlled by oral prednisolone 25

mg per day. He otherwise felt well and on

examination seemed to be in good general

health. An enlarged lymph node was found in

his left axilla. Visual acuity was 6/6 in the right
eye and 6/5 in the left eye. Examination of the

anterior segment in the right eye revealed a

latent cataract or retinal detachment. His creatinine

levels were found to be raised at 253 µmol/l,

and lactate dehydrogenase at 443 IU/l. Urine examination showed

both blood and protein present.

A diagnosis of cutaneous malignant melanoma with simultaneous metastases to the conjunctiva and choroid was made. The patient was counselled and referred to the oncologist.

Simultaneous metastases of cutaneous malignant melanoma to conjunctiva and choroid

Simultaneous metastases of cutaneous malignant melanoma to conjunctiva and choroid

Editor—We report an unusual case of a cutaneous malignant melanoma which metas-
tasised to the conjunctiva in one eye and the choroid in both eyes nearly 2 years after the

initial presentation.

A 42 year old white man presented with a his-
tory of a small superficial black mark in the

temporal aspect of the right eye, which had

infiltrate seen at the edges. It had been excised

completely with no vascular or lymphatic

infiltration seen in the section. He had been

thoroughly screened and a computed tomo-

gram (CT) scan of the abdomen and head

had revealed no metastases. Subse-
dently, he had been followed up on a 4

monthly basis over the next 2 years and no

recurrences had been found. During this

period he developed a severe form of asthma

which was controlled by oral prednisolone 25

mg per day. He otherwise felt well and on

examination seemed to be in good general

health. An enlarged lymph node was found in

eye and 6/5 in the left eye. Examination of the

anterior segment in the right eye revealed a

latent cataract or retinal detachment. His creatinine

levels were found to be raised at 253 µmol/l,

and lactate dehydrogenase at 443 IU/l. Urine examination showed

both blood and protein present.

A diagnosis of cutaneous malignant melanoma with simultaneous metastases to the conjunctiva and choroid was made. The patient was counselled and referred to the oncologist.
Acute sixth nerve palsy in vitamin A treatment of xerophthalmia

EDITOR,—Vitamin A deficiency remains a leading cause of blindness worldwide with xerophthalmia affecting 5–10 million children, resulting in 250 000–500 000 new cases of blindness each year. In the developed world, vitamin A deficiency is rare and usually occurs in the setting of malabsorptive states (such as cystic fibrosis and small bowel disease), liver disease, or malnutrition. Xerophthalmia is a medical emergency carrying a high risk of blindness, infection and death. Immediate administration of high doses of vitamin A is required. Such rapid restoration of vitamin status is felt to be extremely safe at recommended doses. Appropriate dosing regimens in infants have been less clear than in older children and adults.1 Reports of side effects are limited, and therefore we report a case of acute sixth nerve palsy in an infant receiving intramuscular vitamin A for xerophthalmia secondary to cystic fibrosis.

CASE REPORT
A 5 month old male infant with a long history of feeding intolerance was admitted to our hospital for severe irritability and failure to thrive. In the course of his examination, a sweat test was performed confirming the diagnosis of cystic fibrosis. Appropriate nutritional therapy and pancreatic enzyme replacement was commenced. The infant had also been treated by his paediatrician for “conjunctivitis” of his right eye for the preceding 2 months with topical antibiotics. On the ophthalmic examination, the infant’s visual acuity was fix and follow bilaterally. Extraocular motility was full and the eyes were orthophoric. Anterior segment examination revealed conjunctival xerosis of both eyes, and an inferior corneal ulcer of the right eye measuring 2×4 mm. Fundus examination was normal in both eyes. A diagnosis of xerophthalmia was made.

Vitamin A therapy was promptly commenced, with 50 000 IU (water miscible retinyl palmitate) intramuscularly to be given immediately and then to be repeated on the following day. After the first 50 000 IU, prominent bulging of the fontanelle was observed, although the infant remained alert and happy, and was feeding well. The second dose of 50 000 IU was therefore postponed for 48 hours, to be administered in two divided doses over 2 consecutive days. These doses were well tolerated, with gradual improvement of the bulging fontanelle within a week. Five days after the initial vitamin A dose, a complete abduction deficit of the infant’s left eye was noted, in keeping with an acute sixth nerve palsy of the left eye. The infant still remained alert and happy, and

there were no other signs of raised intracranial pressure. The corneal ulcer of the right eye was fully healed at this time. The infant was followed for 2 months over which time the sixth nerve palsy fully resolved. There were no other neurological sequelae. The infant continued to receive oral vitamin A supplementation after discharge.

COMMENT
Prompt mega-dose administration of vitamin A is essential in the management of xerophthalmia. Oral administration is preferred because of its safety, cost, and effectiveness. The recommended regimen is 200 000 IU of vitamin A on the day of diagnosis, the next day, and 4 weeks later. In the rare instances in which children are unable to swallow or absorb oral vitamin A, intramuscular injection of water miscible retinyl palmitate 55 mg (100 000 IU) should be substituted—given immediately, the next day, and 4 weeks later. Children 6–11 months of age should receive half these doses and children less than 6 months of age one quarter of these doses. In our patient, because the child’s age was approaching 6 months, we chose to administer 50 000 IU doses.

Acute vitamin A toxicity generally occurs in children when a single dose greater than 330 000 IU is ingested, although some infants can be adversely affected by single doses as low as 100 000 IU. Typical features include a bulging fontanelle in infants, raised cerebrospinal fluid (CSF) pressure, nausea and vomiting, vertigo, and blurred vision or diplopia. These side effects are generally transient and subside within 1–2 days. Chronic ingestion of large amounts of vitamin A can result in psychotomie cerebri.

This case demonstrates acute toxicity occurring after a cumulative dose of 100 000 IU given over 4 days. The sixth nerve palsy occurred presumably from raised CSF pressure, a phenomenon that is not fully understood but is due to altered CSF resorption or production. Acute toxicity from intramuscular vitamin A (particularly water miscible forms) may be more likely because of the higher serum levels that are achieved more rapidly compared with oral preparations. Nevertheless, this case attests to the relative safety of vitamin A administration in infants.

Successful treatment of ocular invasive mould infection (fusariosis) with the new antifungal agent voriconazole

EDITOR—Voriconazole is a new, highly potent, triazole with broad spectrum activity against fungi, including moulds, as well as fluconazole resistant Candida spp.1 Like other azole antifungal agents it interferes with ergosterol biosynthesis. Its antifungal activity has been shown in several experimental as well as clinical studies.2

CASE REPORT
In November 1998, a 16 year old girl was transferred to the university eye hospital in Duesseldorf with a severe ulcerative hypopyon keratitis in the left eye from which she had been suffering for 3 months after swimming in a lake in Italy. Smears, scrapings, and serology gave no hint of the aetiology. Despite intensive topical antibacterial, anti-achanthamoebal, antifungal, and antitherpeutic, as well as cryoapplication, her clinical situation had deteriorated continuously before admission to our hospital. As an optical rehabilitation was unlikely, owing to the severely infiltrated cornea, a perforating keratoplasty was performed. Postoperatively, the patient was given systemic as well as topical antibiotics. The first 3 days postoperatively were inconspicuous, but from the sixth day on a hypopyon could again be seen. The hypopyon progressed and we could identify, by ultrasound biomicroscopy the focus at the remaining recipient cornea. We removed this focus which was highly suspected of being a fungal colony and sent it to the microbiology department (an attempt to culture bacteria or fungi failed). Antifungal therapy with systemic fluconazole (200 mg/day intravenously) and topical amphotericin B (0.3% every hour) were started, but the clinical picture still deteriorated. At that time a filamentous fungus was diagnosed histopathologically in the excised corneal button (Fig 1). Because of the morphological similarities between Aspergillus, Fusarium, and Pseudallescheria boydii on histology these potent causes of keratitis could not be differentiated by this technique alone. Immunohistochemical examination of mycelia containing tissue sections with a panel of specific antifungal antibodies, all Grocott methenamine silver positive hyphae were identified as Fusarium species because a strong and uniform reactivity was obtained only with a heterologously absorbed polyclonal antibody raised towards somatic antigens of Fusarium solani.3

As the antifungal therapy had no effect whatsoever, the regimen was changed to systemic iraconazole (Semaphore) 200 mg twice daily (a triazole which is known to be effective against some amphotericin B resistant mould species) for 3 days again with no clinical effect.

Owing to the lack of response to conventional therapy, we obtained the new antifungal agent voriconazole, from Pfizer, on an compassionate use basis. Voriconazole was started at a dosage of 6 mg/kg intravenously twice on day 1 followed by 4 mg/kg intravenously twice daily. This well tolerated therapy produced a significant clinical improvement. However, after 10 days the disease relapsed (Fig 2). Owing to the initial positive response it was considered that the relapse might be due to suboptimal penetration to the site of infection. Voriconazole therapy was changed to 6 mg/kg by mouth twice daily. Voriconazole was also injected intracameral, at a dosage of 10 µg/0.1 ml. Topical antifungal therapy was switched from amphotericin B 0.3% every hour to voriconazole 1% every half hour. In addition, any remaining suspicious intrastromal material was again excised and the anterior chamber was irrigated with a 3 µg/ml voriconazole solution. After this procedure, healing finally took place, and the patient was released from hospital; voriconazole was discontinued after 8 weeks. The corneal graft remained clear and best corrected vision was 0.9. There were no local or systemic adverse effects during this highly potent antifungal regimen. A transient elevation of liver enzymes (a known adverse event of azole antymicotics) at the end of therapy and after cessation has been attributed to the study drug. Topical administration was well tolerated.

COMMENT
This is the first time that the efficacy of voriconazole in the treatment of ocular invasive fungal infection has been demonstrated. Topical administration has been tolerated well even when injected into the anterior chamber. Its obvious antifungal activity and favourable pharmacological properties, especially the low range of side effects, will make this new drug attractive for future studies on invasive ocular infections.

Severe intraocular inflammation after a change of HAART

Editor,—Patients with previous cytomegalovirus retinitis (CMVR) and immune recovery vitritis who developed further severe intraocular inflammation 6 weeks after changing HAART (highly active antiretroviral therapy). In vitro comparative efficacy of voriconazole and itraconazole against fluconazole-susceptible and resistant Cryptococcus neoformans isolates. Antimicrob Agents Chemother 1997;41:471–2.

CASE REPORT

A 43 year old man, diagnosed as HIV positive in 1984, was treated in January 1996 for bilateral CMVR that responded to systemic ganciclovir.

In April 1996 he started saquinavir, stavudine, and lamivudine. A viral load was 18 000 copies $10^6$ and CD4+ count 40 cells $10^6$/l. In December 1996 ritonavir was added.

In February 1997 he developed immune recovery vitritis in both eyes. Best corrected visual acuities (BCVA) were 6/6, N5 right; 6/6, N6 left. A viral load was now 7800 copies $10^6$ and CD4+ count 100 cells $10^6$/l. In December 1996 ritonavir was added.

In February 1997 he developed immune recovery vitritis in both eyes. Best corrected visual acuities (BCVA) were 6/6, N5 right; 6/6, N6 left. A viral load was now 7800 copies $10^6$ and CD4+ count 100 cells $10^6$/l. A fluorescein angiogram showed bilateral CMO with macular ischaemia (Fig 1) and he was treated with 230 mg sustained release oral acetazolamide, twice daily. After 1 month’s treatment there was a subjective improvement in vision but no objective change in VA. In September 1997 his BCVAs were 6/6, N5 right; 6/6, N6 left. In December 1997 his CD4+ count was inactive and ganciclovir was stopped.

In February 1998 he developed marked lipodystrophy and consequently was changed to efavirenz, hydroxyurea, didanosine, and continued on stavudine. By April 1998 his viral load had fallen to less than 500 copies $10^1$ and his CD4+ count was 128 cells $10^6$/l (Fig 2).

Six weeks after changing HAART, he complained of blurred left vision. Visual acuity was 6/6 right, 6/9 left. There was a left vitritis with a white retinal lesion along the inferotemporal vessels at the margin of inactive CMVR (Fig 3). A diagnosis of relapse of CMVR was made and he was treated with intravenous ganciclovir.

Two weeks later vision was counting fingers, the vitritis was worse, and the retinal lesion had extended with more haemorrhage. He was treated for presumed toxoplasmosis with sulfadiazine, pyramethamine, and folinic acid but 1 week later his vision was hand movements and the lesion was larger (Fig 4). A diagnostic vitrectomy was performed. Polymerase chain reaction (PCR) was negative for CMV, toxoplasmosis, varicella zoster, and Epstein–Barr viruses. Cytology did not reveal lymphoma.

One week later the eye was painful and vision was perception of light. A retinal biopsy was performed in an area of active inflammation. Histology showed retinal necrosis and exudates. No viral inclusion bodies were found and stains for acid fast bacilli, fungi, and toxoplasma cysts were all negative. A few atypical lymphocytes were seen and PCR for
B cell clonality showed oligoclonal banding. A contrast enhanced magnetic resonance imaging of the brain and orbits was normal.

Eighteen months later the BCVAs were 6/6, N5 right; perception of light, left. A chororietinal scar persists in the macular and temporal retina of the left eye but there is no active inflammation in either eye.

COMMENT

Investigations in this patient failed to identify any cause for the intraocular inflammation; however, the cessation of the inflammatory process in the absence of any specific treatment is similar to the clinical course of immune recovery vitritis and suggests a non-infectious mechanism. The temporal association with changes in HAART, together with the PCR findings, both imply an immunological cause. It is unclear why this response was unilocular.

The presence of multiple discrete bands on PCR may indicate a premalignant lymphoproliferation but 18 months later the eye is quiet with no recurrence and the patient remains well. Our hypothesis is that the intraocular inflammation occurred because the new combination HAART produced a second, very exaggerated immune response to pre-existing antigens.

Clinicians should be aware that changing the combination of HAART may be associated with aggressive intraocular inflammation with an oligoclonal lymphocyte response. Early recognition and treatment with systemic immunosuppression may prevent blindness in our patient.

Oriental herbal medicine induced epithelial keratopathy

EDITOR.—“Kampo” is the name given to an oriental herb medicine which has been used in China and Japan for more than 2000 years. Kampo is believed to be very mild and a safe medicine and so far there has been no report of kampo induced keratopathy.

We report a case of epithelial keratopathy, which occurred in a patient who had taken an oriental herbal medicine for 5 years. To the best of our knowledge, this is the first report of oriental herbal medicine (kampo) induced keratopathy.

CASE REPORT

A 30 year old Japanese woman was referred to Juntendo University Hospital with the complaint of bilateral photophobia. Visual acuity was 20/20 in both eyes. Slit lamp examination disclosed dust-like opacities in the epithelial layer in both central corneas, and brown coloured precipitates, which spread radially from the central cornea (Fig 1A). No corneal staining was observed with fluorescein. No other ocular abnormality was found. There were no remarkable findings in her past or family history.

The patient underwent therapeutic and diagnostic superficial keratectomy that provided epithelial layer for ultrastructural study. The corneal epithelial layer was processed for routine electron microscopy. Electron microscopic examination disclosed corneal epithelial cells with numerous lamellar inclusion bodies formed by series of concentrically arranged lamellae suggestive of lipid-like material (Fig 1B).

The patient was submitted to laboratory tests in order to investigate a possible metabolic disease. No abnormal data were detected except for slightly high level of total blood cholesterol. Concerning the drug history, the patient informed us that she had been taking an oral oriental herbal medicine for chronic constipation for about 5 years. The composition of the drug is shown in Table 1. Two years before the present complaint, the patient had the same symptom of photophobia which gradually disappeared several months after withdrawal of the herbal medicine. One month before the present complaint, she started taking the herbal medicine for constipation. Three months after withdrawal, the corneal opacities decreased and the patient noticed relief of symptoms. One year after withdrawal, the corneal lesions had disappeared completely. No sign of recurrence was observed until now, 4 years after the first examination.

COMMENT

Although oriental herb medicines have been beneficial to patients, scientific explanation of their pharmacological mechanisms has lagged behind the widespread use of kampo in clinical practice.1 In this case, the clinical and morphological findings were similar to those observed in Fabry’s disease2 and in drug induced keratopathy.3 In drug induced lipid storage keratopathy, the corneal deposits are bilateral, dose and duration related, and gradually disappear after the drug is withdrawn.4 Although kampo is believed to be very safe, it seems advisable to dictate caution with respect to this possible adverse effects.

Branch retinal artery occlusion; another complication of sildenafil

EDITOR.—Sildenafil is the oral treatment for erectile dysfunction and was licensed throughout Europe in September 1998. It is a potent, selective inhibitor of the isoenzyme phosphodiesterase type 5 (PDE 5). Inhibition of PDE5 leads to prolongation of cyclic guanosine monophosphate (cGMP) activity in erectile tissue and increases the natural
vessels dilate and improve blood flow.

Whereas many ocular adverse effects of sildenafil have been reported, we present, to the best of our knowledge, the first case report of branch central retinal artery occlusion following the use of sildenafil.

CASE REPORT

A 69 year old man presented with a sudden painless loss of vision in the left eye 2 days previously. The patient was fit and healthy otherwise and had no history of glaucoma, diabetes, hypertension, or other systemic vascular diseases. Visual acuity was 6/6 in the right eye and 6/24 in the left eye. Anterior segment examination was normal apart from a mild relative left afferent pupillary defect. Fundus examination of right eye was normal whereas fundus examination of the left eye revealed a superotemporal branch retinal artery occlusion. As the patient did not have any of the risk factors predisposing to arterial occlusion a more detailed history was sought and the patient informed us that he had taken sildenafil (100 mg) a few hours before he experienced loss of vision in left eye. Since then, he has not used sildenafil.

COMMENT

A number of adverse effects of sildenafil have been reported and these include headache, facial flushing, dyspepsia, and nasal congestion. There have been reports of prolonged erection and priapism, myocardial infarction, sudden cardiac arrest, ventricular arrhythmias, and hypertension. In patients taking organic nitrates, it can lead to a sudden and severe drop in blood pressure. A cardiac examination, including exercise treadmill testing has been recommended before starting patients on sildenafil. Various ocular side effects have been described following the use of sildenafil. These fall into two major categories: (i) those secondary to the weak inhibitory effects of sildenafil on the isoenzyme PDE6 in the retina. These side effects include temporary loss of vision, increased intraocular pressure, green/blue tinging of vision, increased sensitivity to light, and blurred vision. There have also been reports of retinal degeneration. A decrease in the a-wave and b-wave amplitude in the electroretinogram (ERG) of five healthy men 1 hour after oral intake of 100 mg sildenafil has also been reported and these changes completely disappeared 5 hours later. (ii) Ocular vascular events such as haemorrhages, venous occlusion, and anterior ischaemic optic neuropathy have been mentioned but so far there has been no referenced report of retinal artery occlusion following the use of sildenafil. In addition to these ocular side effects, a pupil sparing third nerve palsy due to sildenafil has also been reported. In the case reported here, a sudden rise in intraocular pressure or an embolic phenomenon due to short lived cardiac arrhythmias may have produced branch retinal artery occlusion. This case report clearly suggests that the earlier claim that there is no cause for alarm over retinal side effects of sildenafil must be re-examined and a potentially blinding complication like the one reported here should be seriously considered and discussed with all the patients started on sildenafil, more so because of the fact that most of the patients using this medication are already at high risk of developing vascular accidents in the body.
