Bilateral cavernous haemangiomas of the orbit

EDITOR,—The great majority of orbital tumours are unilateral. However, some conditions, such as idiopathic orbital inflammation (“pseudotumour”), granulomatous inflammation, lymphoid tumours, or metastases sometimes can be bilateral. Orbital cavernous haemangioma is almost always unilateral.1 2 We report a patient with bilateral orbital cavernous haemangiomas that caused unilateral proptosis and visual distortion.

CASE REPORT
A 37 year old man developed distorted vision in the inferior field of his left eye and was found to have mild left proptosis. There was mild swelling of the left optic disc and a small inferonasal visual field defect. Orbital computed tomography (CT) revealed bilateral orbital masses and the patient was referred to the oncology service for another opinion and orbital masses and the patient was referred to the oncology service for another opinion and management. His visual acuity was 6/6 in each eye and colour vision was normal in both eyes. The only positive findings were 3 mm of left proptosis, mild swelling of the left optic disc, and a subtle inferonasal field defect. The orbital CT showed a round, soft tissue mass in the left orbit temporally that displaced the retrolubar portion of the optic nerve nasally. A similar but smaller mass was present in the right orbit lateral to the medial rectus muscle (Fig 1). Both masses showed slight contrast enhancement. The clinical diagnosis was bilateral cavernous haemangioma. The left orbital mass was removed intact by a superolateral extraconal approach. Gross and microscopic studies revealed a benign tumour composed of large endothelial lined vascular channels separated by fibrous stroma, consistent with cavernous haemangioma (Fig 2). The patient had an unremarkable postoperative course with good visual acuity.

COMMENT
Cavernous haemangiomas of the orbit is a common, benign tumour that almost always occurs unilaterally. There are rare reports of bilateral orbital cavernous haemangiomas. Fries and Char reported a case that was very similar to ours.3 They excised the tumour in one orbit and elected to follow the asymptomatic tumour in the opposite orbit. Sullivan and associates reported an unusual case of multiple bilateral orbital haemangiomas.4 Johnson and co-workers reported bilateral orbital haemangiomas as part of Maffucci's syndrome, a condition characterised by chondromatosis and multiple systemic haemangiomas.5 Our patient was otherwise normal with no evidence of Maffucci's syndrome. There was also a recent report of bilateral orbital vascular masses, presumed orbital varices, that caused intravascular papillary endothelial hyperplasia.6 The widespread use of CT and magnetic resonance imaging to evaluate unrelated problems, such as headache, has led to the recognition of asymptomatic lesions compatible with orbital cavernous haemangioma. We have seen several such cases and have elected to follow without treatment these small, asymptomatic tumours, presumed to be bilateral cavernous haemangiomas. Consequently, it is possible that orbital cavernous haemangioma may be more common than previously believed. If so, additional cases of bilateral orbital cavernous haemangioma will probably be recognised. In our case, the asymptomatic tumour in the right orbit most likely is a cavernous haemangioma, but periodic observation, rather than surgical excision, would seem to be the best management.

Choroidal neovascularisation at a demarcation line: an immunopathological study

EDITOR.—We describe a patient presenting with choroidal neovascular membrane (CNVM) at the demarcation line of a longstanding rhegmatogenous retinal detachment (RRD), and characterise its immunopathological features following surgical removal.

CASE REPORT
A 46 year old myopic woman attended the vitreoretinal service with a 3 month history of a shadow in the superior half of her left visual field. Her visual acuity was 6/9 right and 6/12 left, with a refractive error of −13.0D and −9.50D effective spheres respectively.

Examination of the left fundus revealed longstanding detached and thinned retina inferiorly and a broad heavily pigmented demarcation line passing through the macula with associated retinal pigment epithelial (RPE) hypertrophy. An area of parovascular retina adjacent to the tide mark appeared elevated and a fundus fluorescein angiogram

Br J Ophthalmol 1999;84:928–935
(FFA) revealed a juxtafoveal CNVM emerging from the edge of RPE hypertrophy. Three months later she reported decreased vision and metamorphopsia in her left eye, with a best corrected left visual acuity reduced to counting fingers. A subfoveal extension of the CNVM with bordering haemorrhage was present, confirmed by FFA (Fig 1A, B). She subsequently underwent pars plana vitrectomy, parafoveal retinotomy, and removal of subfoveal CNVM, together with external scleral buckling, argon laser retinopexy, and 20% sulphur hexafluoride gas tamponade.

Postoperatively, an area of inferior retinal detachment persisted and further surgery with silicone oil tamponade was undertaken. Subsequently, a posterior subcapsular cataract developed and she underwent left phacoemulsification with intraocular lens implantation and removal of silicone oil. Postoperatively, visual acuity improved to 6/18 and the retina remained flat with no clinically apparent CNVM (Fig 1C). Four months later, her visual acuity was reduced to 6/36. Fundal examination showed an elevated area at her fovea and FFA confirmed a recurrent CNVM.

The distribution of basic fibroblast growth factor (bFGF), vascular endothelial growth factor (VEGF), macrophages (PGM1), and von Willebrand factor (vWF) were investigated using a standard biotin-streptavidin-biotin, alkaline phosphatase complex method (Dako Ltd). The alkaline phosphatase label was visualised as a red final reaction product (Vector Ltd). Nuclei were weakly stained with Mayer’s haematoxylin. A normal human donor eye was used as a positive control, while the negative control used was normal rabbit serum diluted to give a final protein concentration equivalent to that of the primary antibody used.

Histopathological examination revealed a CNVM consisting of numerous endothelial lined vascular channels and chronic inflammatory cells. The CNVM was lined by an incomplete layer of RPE cells on its posterior aspect, as determined by the clinical orientation of the membrane at the time of removal (Fig 2A).

A large portion of the CNVM consisted of vascular channels lined by endothelial cells displaying immunoreactivity for von Willebrand antigens (Fig 2B). There was staining for VEGF (Fig 2C) and bFGF (Fig 2D) in the extracellular matrix, with a similar distribution of immunoreactivity.

COMMENT

Choroidal neovascularisation occurs in a wide spectrum of conditions, including degenerative, inflammatory, traumatic, and hereditary disorders—all characterised by breaks in Bruch’s membrane. A few cases of CNVM developing at the edge of a demarcation line have been reported in both chronic rhegmatogenous and tractional retinal detachments; however, the immunopathology does not appear to have been previously described. A demarcation line (“high watermark”) is characteristically found in longstanding retinal detachments that either progress very slowly or remain static. In this setting, RPE cells may detach from Bruch’s membrane to proliferate and undergo metaplasia in the subretinal space at the junction of attached and detached retina. Clinically, a demarcation line appears as a line of increased pigmentation in this area and may form a sufficiently firm adhesion to prevent progression of a retinal detachment. The local wound healing response at the edge of the detached retina may also lead to excessive RPE proliferation. In our patient, such chorioretinal adhesion may have allowed the transmission of mechanical vitreoretinal traction forces to Bruch’s membrane. This could potentially have compromised the integrity of Bruch’s membrane, allowing the formation of a CNVM. High myopia was a further predisposing factor for choroidal neovascularisation in this patient, making Bruch’s membrane more susceptible to disruption.

Grossniklaus and Gass have described two fundamentally different types of choroidal neovascular growth patterns—type 1, with growth of new vessels beneath the retinal pigment epithelium, and type 2, with growth of new vessels in the sub-sensory retinal space. In our patient, the presence of RPE cells on the posterior surface of the CNVM indicates that it represented a type 2 membrane, as determined by its clinical orientation at the time of removal.

Experimentally detached retina in cats has been shown to possess higher angiogenic activity than normal attached retina. Indeed, peripheral retinal neovascularisation has been described in chronic rhegmatogenous retinal detachment. Retinal detachment is likely to lead to compromised metabolism and hypoxia of the outer retinal layers due to elevation of the retina from the choroid. RPE cells may

www.bjophthalmol.com
Melanoma, earlier he had had a large malignant melanoma to conjunctiva and choroid in both eyes nearly 2 years after the initial presentation. During this period he developed a severe form of asthma which was controlled by oral prednisolone 25 mg per day. He otherwise felt well and on examination seemed to be in good general health. An enlarged lymph node was found in his left axilla. Visual acuity was 6/6 in the right eye and 6/5 in the left eye. Examination of the anterior segment in the right eye revealed a small superficial blackish brown mark about 3 mm in size on the lateral aspect of the bulbar conjunctiva. Left eye anterior segment examination was normal. The intraocular pressure was 17 mm Hg in both the eyes. Fundus examination of both the eyes revealed multiple, widespread, irregular subretinal pigment epithelial membranes, some flat and some elevated. There was no associated cataract or retinal detachment. His creatinine levels were found to be raised at 253 µmol/l, urea at 14.5 mmol/l, and lactate dehydrogenase at 443 IU/l. Urine examination showed both blood and protein present.

A diagnosis of cutaneous malignant melanoma with simultaneous metastases to the conjunctiva and choroid and possible widespread metastases was made. The patient was counselled and referred to the oncologist.

Simultaneous metastases of cutaneous malignant melanoma to conjunctiva and choroid

Editor.—We report an unusual case of a cutaneous malignant melanoma which metastasised to the conjunctiva in one eye and the choroid in both eyes nearly 2 years after the initial presentation.

CASE REPORT
A 42 year old white man presented with a history of a small superficial black mark in the temporal aspect of the right eye, which had increased in size for the past 2 months. There was no significant ocular history. Two years earlier he had had a large malignant melanoma, 4.5 × 3.5 cm, removed from his lower back. On histopathology, this had been diagnosed as a superficial spreading type (Clark’s level IV with Breslow thickness of 3.5 mm). The mitotic count was 5 per 10 high power field (HPF) with a sparse lymphocytic infiltrate seen at the edges. It had been excised completely with no vascular or lymphatic invasion seen in the section. He had been thoroughly screened and a computed tomograph (CT) scan of the abdomen and head had not revealed any metastases. Subsequently, he had been followed up on a 4 monthly basis over the next 2 years and no recurrences had been found. During this period he developed a severe form of asthma which was controlled by oral prednisolone 25 mg per day. He otherwise felt well and on examination seemed to be in good general health. An enlarged lymph node was found in his left axilla. Visual acuity was 6/6 in the right eye and 6/5 in the left eye. Examination of the anterior segment in the right eye revealed a small superficial blackish brown mark about 3 mm in size on the lateral aspect of the bulbar conjunctiva. Left eye anterior segment examination was normal. The intraocular pressure was 17 mm Hg in both the eyes. Fundus examination of both the eyes revealed multiple, widespread, irregular subretinal pigment epithelial membranes, some flat and some elevated. There was no associated cataract or retinal detachment. His creatinine levels were found to be raised at 253 µmol/l, urea at 14.5 mmol/l, and lactate dehydrogenase at 443 IU/l. Urine examination showed both blood and protein present.

A diagnosis of cutaneous malignant melanoma with simultaneous metastases to the conjunctiva and choroid and possible widespread metastases was made. The patient was counselled and referred to the oncologist.
present with pain and redness due to second-
dary glaucoma caused by infiltration of the
trabecular meshwork or angle closure due to an
annular haemorrhagic choroidal detachment.6 Retinal deposits are very rare and may cause blurred vision.7 Differentiation between secondary melanomas in the choroid and a primary melanoma is important in order to
decide on the type of management. Bilateral diffuse uveal melanocytic prolifera-
tion is an important differential diagnosis in our patient but he had no associated cataract, retinal detachment, or severe visual impair-
tment. The time interval between the initial presentation of the skin lesion and the occur-
dence of metastases may vary from months up to 10 years.8 The occurrence of uveal metastases usually indicates grave prognosis owing to widespread visceral disease, as was the case in our patient. He had undergone regular thorough screening for 2 years but the signs of metastases were found during this period. The first external sign of secondary
disease was the presence of the conjunctival
lesion, which led to the discovery of the intracu-
lcular metastatic tumour cell deposit. A palpable node, involvement. Metastases to the conjunctiva from a cutaneous malignant melanoma is again very rare (less than 1%) and is usually associated with secondaries elsewhere in the
eye.4 These metastases need to be differentiated from other conditions such as primary acquired
melanosis, naevus, adrenochrome deposits, direct extensions from ciliary body melanomas,
and foreign body granulomas. The mode of
treatment of metastatic cutaneous malignant
melanoma in the eye can range from local excision as in small localised iris tumours, and enucleation for a painful blind eye or palliative treatment employing chemo-
therapy and radiotherapy if the disease is widespread, as is often the case.9 Patients with a
single choroidal metastasis may be consid-
ered for radioactive plaque treatment.10 Previ-
ous studies have reported a median survival rate of 72 days with a maximum survival of
183 days and less than 10% survive up to 8 months after the onset of ocular symptoms.11 Although the survival rates are partly related to the
depth of the dermal invasion12 ocular metastases with only superficial spreading type of melanomas have been reported and
this was also true of our patient. Within days
of being diagnosed with uveal metastases,
he developed signs of widespread sec-
ondaries, which led to his death within
weeks.

Acute sixth nerve palsy in vitamin A
treatment of xerophthalmia

EDITOR,—Vitamin A deficiency remains a
leading cause of blindness worldwide. Xer-
ophthalmia affecting 5–10 million children,
results in 250 000–500 000 new cases of
blindness every year. In the developed
world, vitamin A deficiency is rare and usually
occurs in the setting of malabsorption (such as cystic fibrosis and small bowel
disease), liver disease, or malnutrition.
Xerophthalmia is a medical emergency
carrying a high risk of blindness, infection and
death. Immediate administration of high doses of vitamin A is required. Such rapid res-
toration of vitamin status is felt to be
terribly at recommended doses. Appropriate
dosing regimens in infants have been
less clear than in older children and adults.1 Reports of side effects are limited, and
therefore we report a case of acute sixth nerve
palsy in an infant receiving intramuscular vitamin A for xerophthalmia secondary to
cystic fibrosis.

CASE REPORT
A 5 month old male infant with a long history of
feeding intolerance was admitted to our hospital for severe irritability and failure to
thrive. In the course of his examination, a
swell test was performed confirming the diag-
osis of cystic fibrosis. Appropriate nutritional
therapy and pancreatic enzyme replacement
was commenced. The infant had also been treated by his pae-
diatrian for “conjunctivitis” of his right eye
for the preceding 2 months with topical antibiotics. On the ophthalmic examination, the
infant’s visual acuity was fix and follow
bilaterally. Extraocular motility was full and
the eyes were orthophoric. Anterior segment
examination revealed conjunctival xerosis of
both eyes, and an inferior corneal ulcer of
the right eye measuring 2×4 mm. Fundus exam-
nation was normal in both eyes. A diagnosis of
xerophthalmia was made.

Vitamin A therapy was promptly com-
menced, with 50 000 IU (water miscible reti-
nyl palmitate) intramuscularly to be given
immediately and then to be repeated on the
following day. After the first 50 000 IU, prominent bulging of the fontanelle was observed, although the infant remained alert
and happy, and was feeding well. The second
dose of 50 000 IU was therefore postponed
for 48 hours, to be administered in two
divided doses over 2 consecutive days. These
doses were well tolerated, with gradual
development of right sided ptosis, which was
 noticed, although the infant remained alert
and happy, and...
there were no other signs of raised intracranial pressure. The corneal ulcer of the right eye was fully healed at this time. The infant was followed for 2 months over which time the sixth nerve palsy fully resolved. There were no other neurological sequelae. The infant continued to receive oral vitamin A supplementation after discharge.

COMMENT

Prompt mega-dose administration of vitamin A is essential in the management of xerophthalmia. Oral administration is preferred because of its safety, cost, and effectiveness. The recommended regimen is 200 000 IU of vitamin A on the day of diagnosis, the next day, and 4 weeks later. In the rare instances in which children are unable to swallow or absorb oral vitamin A, intramuscular injection of water miscible retinyl palmitate 55 mg (100 000 IU) should be substituted—given immediately, the next day, and 4 weeks later. Children 6–11 months of age should receive one quarter of these doses.

Acute vitamin A toxicity generally occurs in children when a single dose greater than 330 000 IU is ingested, although some infants can be adversely affected by single doses as low as 100 000 IU.1 Typical features include a bulging fontanelle in infants, raised cerebrospinal fluid (CSF) pressure, nausea and vomiting, vertigo, and blurred vision or diplopia. These side effects are generally transient and subside within 1–2 days. Chronic ingestion of large amounts of vitamin A can result in pseu- dotumour cerebri.

This case demonstrates acute toxicity occurring after a cumulative dose of 100 000 IU given over 4 days. The sixth nerve palsy occurred presumably from raised CSF pressure, a phenomenon that is not fully understood but may be due to altered CSF resorption or production.2 Acute toxicity from intramuscular vitamin A (particularly water miscible forms) may be more likely from intramuscular injection of vitamin A administered to neonates. Vitamin A intoxication on intracranial pressure and brain water in rats. J Nutr 1974;104:478–82.

Successful treatment of ocular invasive mould infection (fusariosis) with the new antifungal agent voriconazole

EDITOR,—Voriconazole is a new, highly potent, triazole with broad spectrum activity against fungi, including moulds, as well as fluconazole resistant Candida spp.1 Like other azole antifungal agents it interferes with ergosterol biosynthesis. Its antifungal activity has been shown in several experimental as well as clinical studies.2

CASE REPORT

In November 1998, a 16 year old girl was transferred to the university eye hospital in Duesseldorf with a severe ulcerative hypopyon keratitis in the left eye from which she had been suffering for 3 months after swimming in a lake in Italy. Smears, scrapings, and serology gave no hint of the aetiology. Despite intensive topical antibacterial, anti-acanthamoebal, antifungal, and antitherpeitic therapy, as well as cryoapplication, her clinical situation had deteriorated continuously before admission to our hospital. As an optical rehabilitation was unlikely, owing to the severely infiltrated cornea, a perforating keratoplasty was performed. Postoperatively, the patient was given systemic as well as topical antibiotics. The first 3 days postoperatively were inconspicuous, but from the sixth day on a hypopyon could again be seen. The hypopyon progressed and we could identify, by ultrasound biomicroscopy, the focus at the remaining recipient cornea. We removed this focus which was highly suspected of being a fungal colony and sent it to the microbiology department (an attempt to culture bacteria or fungi failed). Antifungal therapy with systemic fluconazole (200 mg/day intravenously) and topical amphotericin B (0.3% every hour) was started, but the clinical picture still deteriorated. At that time a filamentous fungus was diagnosed histopathologically in the excised corneal button (Fig 1). Because of the morphological similarities between Aspergillus niger, Fusarium solani, and Pseudallescheria boydii on histology these potent causes of keratitis could not be differentiated by this technique alone. Immunohistochemical examination of mycelia containing tissue sections with a panel of specific antifungal antibodies, all Grocott methanamine silver positive hyphae were identified as Fusarium species because a strong and uniform reactivity was obtained only with a heterologously absorbed polyclonal antibody raised towards somatic antigens of Fusarium solani.3

As the antifungal therapy had no effect whatsoever, the regimen was changed to systemic iraconazole (Sempera) 200 mg twice daily (a triazole which is known to be effective against some amphotericin B resistant mould species) for 3 days again with no clinical effect.

Owing to the lack of response to conventional therapy, we obtained the new antifungal agent voriconazole, from Pfizer, on a compassionate use basis. Voriconazole was started at a dosage of 6 mg/kg intravenously twice on day 1 followed by 4 mg/kg intravenously twice daily. This well tolerated therapy produced a significant clinical improvement. However, after 10 days the disease relapsed (Fig 2).

Owing to the Initial positive response it was considered that the relapse might be due to suboptimal penetration to the site of infection. Voriconazole therapy was changed to 6 mg/kg by mouth twice daily. Voriconazole was also injected intracameraly, at a dosage of 10 µg/0.1 ml. Topical antifungal therapy was switched from amphotericin B 0.3% every hour to voriconazole 1% every half hour. In addition, any remaining suspicious intracorneal material was again excised and the anterior chamber was irrigated with a 3 µg/ml voric- nazole solution. After this procedure, healing finally took place, and the patient was released from hospital; voriconazole was discontinued after 8 weeks. The corneal graft remained clear and best corrected vision was 0.9. There were no local or systemic adverse effects during this highly potent antifungal regimen. A transient elevation of liver enzymes (a known adverse event of azole antymycotic agents) at the end of therapy and after cessation has been attributed to the study drug. Topical administra- tion was well tolerated.

COMMENT

This is the first time that the efficacy of voriconazole in the treatment of ocular invasive fungal infection has been demonstrated. Topical administration has been tolerated well even when injected into the anterior chamber. Its obvious antifungal activity and favourable pharmacological properties, especially the low range of side effects, will make this new drug attractive for future studies on invasive ocular infections.

Severe intraocular inflammation after a change of HAART

EDITOR,—Patients with previous cytomegalovirus retinitis (CMVR) have been observed to get vitritis, cystoid macular oedema (CMO), and epiretinal membranes after commencing HAART (highly active antiretroviral therapy).1,2 It is postulated that this is due to the improved CD4+ function that occurs with HAART.1

We present a patient with previously treated CMVR and immune recovery vitritis who developed further severe intraocular inflammation 6 weeks after changing HAART.

CASE REPORT

A 43 year old man, diagnosed as HIV positive in 1984, was treated in January 1996 for bilateral CMVR that responded to systemic ganciclovir.

In April 1996 he started saquinavir, stavudine, and lamivudine. A viral load was 18 000 copies $\times 10^3$/l and CD4+ count 40 cells $\times 10^6$/l. In December 1996 ritonavir was added.

In February 1997 he developed immune recovery vitritis in both eyes. Best corrected visual acuities (BCVA) were 6/6, N5 right; 6/6, N6 left. A viral load was now 7800 copies $\times 10^3$/l and CD4+ count 100 cells $\times 10^6$/l. A fluorescein angiogram showed bilateral CMO with macular ischaemia (Fig 1) and he was treated with 250 mg sustained release oral acetzolamide, twice daily. After 1 month’s treatment there was a subjective improvement in vision but no objective change in VA. In September 1997 his BCVAs were 6/6, N5 right; 6/6, N6 left. In December 1997 his CMVR was inactive and ganciclovir was stopped.

In February 1998 he developed marked lipodystrophy and consequently was changed to efavirenz, hydroxyurea, didanosine, and continued on stavudine. By April 1998 his viral load had fallen to less than 500 copies $\times 10^3$/l and his CD4+ count was 128 cells $\times 10^6$/l (Fig 2).

Six weeks after changing HAART, he complained of blurred left vision. Visual acuity was 6/6 right, 6/9 left. There was a left vitritis with a white retinal lesion along the inferotemporal vessels at the margin of inactive CMVR (Fig 3). A diagnosis of relapse of CMVR was made and he was treated with intravenous ganciclovir.

Two weeks later vision was counting fingers, the vitritis was worse, and the retinal lesion had extended with more haemorrhage. He was treated for presumed toxoplasmosis with sulphadiazine, pyrametamine, and folinic acid but 1 week later his vision was hand movements and the lesion was larger (Fig 4). A diagnostic vitrectomy was performed. Polymerase chain reaction (PCR) was negative for CMV, toxoplasmosis, varicella zoster, and Epstein–Barr viruses. Cytology did not reveal lymphoma.

One week later the eye was painful and vision was perception of light. A retinal biopsy was performed in an area of active inflammation. Histology showed retinal necrosis and exudates. No viral inclusion bodies were found and stains for acid fast bacilli, fungi, and toxoplasma cysts were all negative. A few atypical lymphocytes were seen and PCR for...

Epidithelial keratopathy
Oriental herbal medicine induced
Early recognition and treatment with systemic
combination HAART produced a second, very
irritation of the brain and orbits was normal.

In investigations in this patient failed to identify
any cause for the intraocular inflammation;
the patient was advised to withdraw
the herbal medicine. Three months after with-
gradually disappear after the drug is
bilateral, dose and duration related, and
storage keratopathy, the corneal deposits are

Although kampo is believed to be
very safe, it seems advisable to dictate caution
with respect to this possible adverse effects.

Oriental herbal medicine induced
epithelial keratopathy

EDITOR,—“Kampo” is the name given to an
oriental herb medicine which has been used in
China and Japan for more than 2000 years. Kampo is believed to be very mild and a safe
medicine and so far there has been no report of kampo induced keratopathy.

We report a case of epithelial keratopathy,
which occurred in a patient who had taken
oriental herbal medicine for 5 years. To the
best of our knowledge, this is the first
report of oriental herbal medicine (kampo) induced keratopathy.

CASE REPORT
A 30 year old Japanese woman was referred to
Juntendo University Hospital with the com-
plaint of bilateral photophobia. Visual acuity
was 20/20 in both eyes. Slit lamp examination
disclosed dust-like opacities in the epithelial
layer in both central corneas, and brown
coloured precipitates, which spread radially
from the central cornea (Fig 1A). No corneal
staining was observed with fluorescein. No
other ocular abnormality was found. There
were no remarkable findings in her past or
family history.

The patient underwent therapeutic and
diagnostic superficial keratectomy that pro-
vided epithelial layer for ultrastructural study.
The corneal epithelial layer was processed for
routine electron microscopy. Electron micro-
scopic examination disclosed corneal epitel-
ial cells with numerous lamellar inclusion
bodies formed by series of concentrically
arranged lamellae suggestive of lipid-like
material (Fig 1B).

The patient was submitted to laboratory
tests in order to investigate a possible meta-
bolic disease. No abnormal data were detected
except for slightly high level of total blood
cholesterol. Concerning the drug history, the
patient informed us that she had been taking
an oral oriental herbal medicine for chronic
constipation for about 5 years. The composi-
tion of the drug is shown in Table 1. Two years
before the present complaint, she
started taking the herbal medicine for consti-
tion. The patient was advised to withdraw
the herbal medicine. Three months after
withdrawal, the corneal opacities decreased and
the patient noticed relief of symptoms. One
year after withdrawal, the corneal lesions had
disappeared completely. No sign of recurrence
was observed until now, 4 years after the first
examination.

COMMENT
Although oriental herb medicines have been
beneficial to patients, scientific explanation of
their pharmacological mechanisms has lagged
behind the widespread use of kampo in
clinical practice. In this case, the clinical and morphological findings were similar to those
observed in Fabry’s disease and in drug
induced keratopathy. In drug induced lipid
storage keratopathy, the corneal deposits are
bilateral, dose and duration related, and
gradually disappear after the drug is
withdrawn. Although kampo is believed to be
very safe, it seems advisable to dictate caution
with respect to this possible adverse effects.

constipation for about 5 years. The composi-
tion of the drug is shown in Table 1. Two years
before the present complaint, she
started taking the herbal medicine for consti-
tion. The patient was advised to withdraw
the herbal medicine. Three months after
withdrawal, the corneal opacities decreased and
the patient noticed relief of symptoms. One
year after withdrawal, the corneal lesions had
disappeared completely. No sign of recurrence
was observed until now, 4 years after the first
examination.

COMMENT
Although oriental herb medicines have been
beneficial to patients, scientific explanation of
their pharmacological mechanisms has lagged
behind the widespread use of kampo in
clinical practice. In this case, the clinical and morphological findings were similar to those
observed in Fabry’s disease and in drug
induced keratopathy. In drug induced lipid
storage keratopathy, the corneal deposits are
bilateral, dose and duration related, and
gradually disappear after the drug is
withdrawn. Although kampo is believed to be
very safe, it seems advisable to dictate caution
with respect to this possible adverse effects.

Oriental herbal medicine induced
epithelial keratopathy

EDITOR,—“Kampo” is the name given to an
oriental herb medicine which has been used in
China and Japan for more than 2000 years. Kampo is believed to be very mild and a safe
medicine and so far there has been no report of kampo induced keratopathy.

We report a case of epithelial keratopathy,
which occurred in a patient who had taken
oriental herbal medicine for 5 years. To the
best of our knowledge, this is the first
report of oriental herbal medicine (kampo) induced keratopathy.

CASE REPORT
A 30 year old Japanese woman was referred to
Juntendo University Hospital with the com-
plaint of bilateral photophobia. Visual acuity
was 20/20 in both eyes. Slit lamp examination
disclosed dust-like opacities in the epithelial
layer in both central corneas, and brown
coloured precipitates, which spread radially
from the central cornea (Fig 1A). No corneal
staining was observed with fluorescein. No
other ocular abnormality was found. There
were no remarkable findings in her past or
family history.

The patient underwent therapeutic and
diagnostic superficial keratectomy that pro-
vided epithelial layer for ultrastructural study.
The corneal epithelial layer was processed for
routine electron microscopy. Electron micro-
scopic examination disclosed corneal epitel-
ial cells with numerous lamellar inclusion
bodies formed by series of concentrically
arranged lamellae suggestive of lipid-like
material (Fig 1B).

The patient was submitted to laboratory
tests in order to investigate a possible meta-
bolic disease. No abnormal data were detected
except for slightly high level of total blood
cholesterol. Concerning the drug history, the
patient informed us that she had been taking
an oral oriental herbal medicine for chronic
constipation for about 5 years. The composi-
tion of the drug is shown in Table 1. Two years
before the present complaint, she
started taking the herbal medicine for consti-
tion. The patient was advised to withdraw
the herbal medicine. Three months after
withdrawal, the corneal opacities decreased and
the patient noticed relief of symptoms. One
year after withdrawal, the corneal lesions had
disappeared completely. No sign of recurrence
vasodilatory actions of nitric oxide on the cavernosal smooth muscle, facilitating the erectile response in men with erectile dysfunction.\(^1\) Whereas many ocular adverse effects of sildenafil have been reported,\(^6\) we present, to the best of our knowledge, the first case report of branch central retinal artery occlusion following the use of sildenafil.

**CASE REPORT**

A 69 years old man presented with a sudden painless loss of vision in the left eye 2 days previously. The patient was fit and healthy otherwise and had no history of glaucoma, diabetes, hypertension, or other systemic vascular diseases. Visual acuity was 6/6 in the right eye and 6/24 in the left eye. Anterior segment examination was normal apart from a mild relative left afferent pupillary defect. Fundus examination of right eye was normal whereas fundus examination of the left eye revealed a superotemporal branch retinal artery occlusion. As the patient did not have any of the risk factors predisposing to arterial occlusion a more detailed history was sought and the patient informed us that he had taken a dose of Viagra (100 mg) a few hours before he experienced loss of vision in left eye. Cardiac examination revealed sinus rhythm, normal heart sounds, and there was no carotid bruit or thrill. Immediate measures taken to restore the circulation (intravenous Diamox, organic nitrates, it can lead to a sudden and severe drop in blood pressure.\(^2\) A cardiac examination, including exercise treadmill testing has been recommended before starting patients on sildenafil.\(^1\) Various ocular side effects have been described following the use of sildenafil. These fall into two major categories: (i) those secondary to the weak inhibitory effects of sildenafil on the isoenzyme PDE6 in the retina.\(^7\) These side effects include temporary loss of vision, increased intraocular pressure, green/blue tinging of vision, increased sensitivity to light, and blurred vision.\(^7\) There have also been reports of retinal degeneration. A decrease in the a-wave and b-wave amplitude in the electroretinogram (ERG) of five healthy men 1 hour after oral intake of 100 mg sildenafil has also been reported and these changes completely disappeared 5 hours later.\(^8\) (ii) Ocular vascular events such as haemorrhages, venous occlusion, and anterior ischaemic optic neuropathy have been mentioned\(^9\) but so far there has been no referenced report of retinal artery occlusion following the use of sildenafil. In addition to these ocular side effects, a pupil sparing third nerve palsy due to sildenafil has also been reported.\(^1\) In the case reported here, a sudden rise in intraocular pressure or an embolic phenomenon due to short lived cardiac arrhythmias may have produced branch retinal artery occlusion. This case report clearly suggests that the earlier claim that there is no cause for alarm over retinal side effects of sildenafil\(^1\) must be re-examined and a potentially blinding complication like the one reported here should be seriously considered and discussed with all the patients started on sildenafil, more so because of the fact that most of the patients using this medication are already at high risk of developing vascular accidents in the body.

**COMMENT**

A number of adverse effects of sildenafil have been reported and these include headache, facial flushing, dyspepsia, and nasal congestion. There have been reports of prolonged erection and priapism, myocardial infarction,\(^3\) sudden cardiac arrest, ventricular arrhythmias, and hypertension.\(^4\) In patients taking organic nitrates, it can lead to a sudden and severe drop in blood pressure.\(^2\) A cardiac examination, including exercise treadmill testing has been recommended before starting patients on sildenafil.\(^1\) Various ocular side effects have been described following the use of sildenafil. These fall into two major categories: (i) those secondary to the weak inhibitory effects of sildenafil on the isoenzyme PDE6 in the retina.\(^7\) These side effects include temporary loss of vision, increased intraocular pressure, green/blue tinging of vision, increased sensitivity to light, and blurred vision.\(^7\) There have also been reports of retinal degeneration. A decrease in the a-wave and b-wave amplitude in the electroretinogram (ERG) of five healthy men 1 hour after oral intake of 100 mg sildenafil has also been reported and these changes completely disappeared 5 hours later.\(^8\) (ii) Ocular vascular events such as haemorrhages, venous occlusion, and anterior ischaemic optic neuropathy have been mentioned\(^9\) but so far there has been no referenced report of retinal artery occlusion following the use of sildenafil.
