Xeroderma pigmentosum in three consecutive siblings of a Nigerian family: observations on ociculocutaneous manifestations in black African children

EDITOR,—Xeroderma pigmentosum (XP), a rare autosomal recessive disorder characterised by defective DNA repair leading to clinical and cellular hypersensitivity to ultraviolet radiation, manifesting mainly as intolerance of skin and eyes to light, has been described in all races,1,2 but is exceedingly rare in the negroid race, although some cases have been reported in both the American3 and African black people.4 We describe three consecutive siblings of a Nigerian, Fulani, family with the typical features of XP. We wish to draw attention to the clinical, phenotypic variations of this syndrome in black children of the same family living together in an area of high sunshine, and the difficulties in the management of XP patients with advanced disease and limited access to facilities in an environment where avoidance of skin exposure to intense ultraviolet rays is problematic. We believe the patients we have described constitute the first series on XP in black children in the West African subregion.

CASE REPORTS

Case 1
The proband, a 9 year old girl, was first seen at Usmanu Danfodiyo University Teaching Hospital (UDUTH), Sokoto (13.02° N, 9.14° E), Nigeria, in February 1999 with a history of the development of generalised erythema of the skin of the limbs, face, and palms) covered with a mixture of mottled, hyperpigmented and hypopigmented, atrophic roundish and oval macules, giving the entire skin a chequered appearance, associated with generalised actinic keratoses (manifesting on black skin as palpalable, rough, blackish spots covered with adherent scales). The actinic keratotic lesions were more numerous on the face. A large reddish ulcerated plaque (2 × 2 cm) with raised, dark, keratotic, sharply demarcated borders was seen on the right cheek and crusted ulceration on the nasal bridge was also noted. Biopsy of the ulcer on the cheek showed well differentiated squamous cell carcinoma. The following lesions were noted in the right eye. The skin of the lids was covered by similar lesions as elsewhere on the skin. The lower lid margin was ulcerated. A conjunctival mass 0.5 × 0.75 cm extended from the medial canthus to and covered the 2–5 o’clock of the limbus. The rest of the limbus was obliterated by a dark, flat lesion. The cornea was hazy because of a fibrovascular membrane on its epithelial surface making it impossible to view structures deeper to it. The left eye also showed loss of all eyelashes of the lower lid and most of those in the upper lid. A large nodular conjunctival lesion (1.5 cm × 1 cm) occupied the whole of the temporal conjunctiva and two thirds of the adjacent cornea. This lesion was pink, firm but friable (see Fig 1). The visual acuity (VA) was perception of light (PL), in the right eye and nil perception of light (NPL), in the left. Biopsy of the conjunctival mass LE showed a moderately differentiated squamous cell carcinoma. On the basis of the characteristic cutaneous and ocular lesions associated with sunshine hypersensitivity and histologically proved squamous cell carcinoma of both the skin and conjunctiva, the diagnosis in the proband was xeroderma pigmentosum in its final phase, the cancerous period.

Case 2
This 7 year old boy, the brother of the proband, presented with milder symptoms of XP with slower progression. Thus, the initial generalised erythematous rash associated with exposure to sunshine became obvious from the age of 3 months; worsening of vision developed from the age of 4 years. The cutaneous lesions, though similar to those in the proband, were less severe. The entire skin was also dry, covered with hyperpigmented and hypopigmented atrophic roundish lesions. The actinic keratotic lesions were less numerous. There were no ulcerations and no cutaneous tumours. The ocular lesions were also milder than in the proband. In the right eye the conjunctiva was xerotic, but without areas of hypertrophy. The cornea was dull, but clear with tendency to dryness. The left eye showed total loss of lashes of the lower lid and hypertrophy of the nasal half of the conjunctiva, with raising of its edge towards the limbus. The VA (6/60 in both eyes) was better than in the proband. The ocular and cutaneous lesions were compatible with xeroderma pigmentosum in the precancerous phase.

Case 3
This was the 5 year old sister of the proband. The onset of the disease and its severity took a middle course between that of the index case (case 1) and the second patient. The onset of erythematous skin lesions and freckles following exposure to sunshine was at age 6 weeks. Hypopigmented and hyperpigmented macules become evident by the age of 2 1/2 years. The actinic keratoses became numerous by age 3 1/2 years and ulcerations of the upper lip was noticed at age 4 1/2 years. The worsening of vision became obvious from the age of 3 years. Ocular examination revealed marked blepharospasm in the right eye, the conjunctiva was generally fleshy, vascular, with a tendency to bleed and covered the cornea in both its nasal half and inferotemporal quadrant. Other corneal areas were covered by a fibrovascular epithelial membrane (Fig 2). Biopsy of the conjunctival mass reveal moderately differentiated squamous cell carcinoma. In the left eye there was total loss of eyelashes of the lower lid, and a vascular fleshy overgrowth of the
conjonctiva covering the whole of the nasal one third of the cornea, and also a small area of the cornea temporally at about 3 o’clock. The VA in the left eye was limited to hand movement only at 2 metres while in the right eye it was PL only. The severity of acinic keratotic lesions was midway between that of the proband and case 2. Although there were crusty skin ulcers of the upper lip, there were no obvious cutaneous tumours. On the basis of these ocular cutaneous lesions, associated with sunshine hypersensitivity and the similarity of the symptomatology with that found in the other two siblings, the diagnosis of xeroderma pigmentosum was not in doubt. The disease in this patient had also advanced to the cancerous phase.

COMMENT

XP is generally regarded as a very serious disease in the tropics because of its pronounced sensitivity to sunlight.1 There was some degree of variation in the severity and rate of progression of the disease in our patients despite their first degree relationship and the common environment characterised by high sunshine. The assertion that the severity of the skin and eye lesions relates more to the degree of skin exposure1 may not explain, entirely, this variation since all the affected children live in a common environment of high sunshine. A recent Japanese study2 has shown that there is correlation of the clinical manifestations and gene mutations even among patients of the same complementation group. We had no facilities in Nigeria to determine the complementation group of our patients and the individual gene mutations of these children. There are many obstacles in Nigeria to the proper management of XP patients in general and the three siblings we have described in particular. Firstly, an elaborate system of photoprotection from birth could not be carried out since there were no facilities for prenatal diagnosis of XP. Secondly, sun exposure could not be altogether avoided and only some measure of protection against the sun was provided—special glasses, clothes, and sunscreen creams. Unfortunately, the management of our patients was limited to these only. Surgical intervention could not be carried out mainly because the cost was too exorbitant for the poor parents. For these patients with advanced disease, limited access to facilities, in an environment of high sunshine, the prognosis is indeed gloomy.

Multifocal electroretinographic and angiographic changes in pre-eclampsia

Editor,—Pre-eclampsia is characterised by hypertension, proteinuria and generalised oedema developed after 20 weeks’ gestation. We report serial changes in multifocal electroretinography (MERG), fluorescein angiography (FA), and indocyanine green angiography (ICGA) in a patient with pre-eclampsia who developed choroidal ischaemia and serous retinal detachment.

CASE REPORT

A 28 year old Chinese woman, gravida II, para I, was hospitalised at 31 weeks’ gestation with hypertension, proteinuria and generalised oedema. At 34 weeks’ gestation, emergency caesarean section was performed because of uncontrolled pre-eclampsia. Two days post partum, she complained of blurring of vision in the right eye. On examination, her visual acuity was right eye: 20/30, left eye: 20/15. There was no afferent pupillary defect. Anterior segment and intraocular pressure was normal. Fundal examination revealed bilateral greyish-yellow lesions at the level of retinal pigment epithelium (RPE), distributed mainly in peripapillary area and posterior pole. There was shallow inferior serous retinal detachment in the right eye. FA and ICGA of both eyes showed early patchy hypofluorescence with delayed filling of choroid around the discs and nasal maculae, suggestive of choroidal ischaemia. Late phase showed leakage with stippled staining (Fig 1).

MERG was performed 2 weeks post partum. Stimulation used was the 103 hexagons m-sequence with visual system (Electro Diagnostic Imaging, Inc, San Mateo, CA, USA). Three dimensional topography and trace array of the MERG showed decreased response amplitudes in both nasal maculae and the right fovea. There was also delayed N1 and P1 implicit times and diminished response density of the nasal macula compared with the temporal macula in both eyes (Fig 2).

Five weeks post partum, her visual acuity improved to 20/15 in both eyes. RPE changes corresponding to areas of delayed filling and leakage were found. FA and ICGA performed 3 months post partum were unremarkable. However, MERG showed persistent bilateral mild decrease in amplitude of the nasal macula compared with the temporal macula, despite full recovery of the right foveal peak. Visual field assessment was not performed.

COMMENT

In our patient, the area of decreased response amplitude and delayed latencies in MERG corresponded with the area of choroidal ischaemia detected by FA and ICGA. Additionally, it detected abnormal area in the right fovea that did not show up with FA or ICGA. When repeat FA and ICGA were unremarkable 3 months later, MERG still showed persistent abnormality in both nasal maculae. The partial recovery of MERG in our case supports the current concept of transient vasospasm in choroidal circulation in pre-eclampsia. However, the damage may not be completely reversible as previously reported.1

www.bjophthalmol.com
The signals of MERG are thought to be derived from the outer retinal layers of cones and also the inner retinal layer including the bipolar and Muller cells. RETA The retinal response may be impaired secondary to RPE dysfunction and choroidal ischaemia. Similar MERG findings in central serous choriretenopathy were reported, in which the RPE abnormality is thought to be secondary to the underlying choroidal vascular disease. MERG has the advantage of being non-invasive and risk of breastfeeding after angiography can be avoided. It is more sensitive than FA and ICG function by multifocal electroretinogram before and after macular hole surgery. Br J Ophthalmol 1999; 83:420-4.

Signet ring cell carcinoma of the eccrine sweat gland in the eyelid, treated by radiotherapy alone

Editor,—The signet ring cell carcinoma of the eccrine sweat gland is a very rare tumour of the eyelid. Only six cases have been published up to now.1 Three patients’ ages ranged from 47 to 78 years. This tumour shares some histological features with breast carcinoma, the metastasis of which represents the most important differential diagnosis—Indian file formations, signet ring cells, and expression of oestrogen, as well as progesterone, receptors. One significant difference is that the positive staining for those hormone receptors is found mainly in the nuclei. The growth fraction was 5%, determined with MIB1.

Different treatment modalities have been applied in cases of eccrine sweat gland carcinoma. Our case demonstrates that tumour control can be achieved with radiotherapy alone despite extensive orbital involvement.

CASE REPORT

An 87 year old male patient was seen initially in our department in July 1998. He had noticed swelling of his right lower eyelid. We saw a diffuse thickening and induration of the right eyelids at initial presentation in our hospital. An magnetic resonance image (MRI) showed a tumour that had infiltrated the upper eyelid (Fig 1) as well as the lower eyelid, the eyebrow, and the perioral muscles. The optic nerve was also surrounded by tumour mass. Two biopsies revealed an infiltrating tumour with Indian file formations; some of the tumour cells had a signet ring appearance with nuclei located peripherally as a result of intracytoplasmic vacuoles. The latter possessed microvilli, as could be demonstrated by electron microscopy. The cytoplasm stained positive with periodic acid Schiff (Fig 2) and with antibodies against oestrogen and progesterone receptors as well as human milk fat globulin. No hormone receptor expression was found in the nuclei. The growth fraction was 5%, determined with MIB1.

Systemic examination did not reveal any other tumour, especially no breast carcinoma and no adenoacarcinoma of the gastrointestinal tract. Two treatment modalities were discussed—orbital exenteration and radiotherapy. Since the patient refused orbital exenteration radiotherapy was started in September and October 1998, and performed over 6 weeks, with a total dosage of 56 Gy. Two months later the cornea showed erosions which were treated with lubricants; the ocular motility was heavily impaired. Fourteen months after radiotherapy the lid skin was soft again without any evidence of tumour recurrence, the cornea only showed irregular epithelium, and the eye motility had returned to almost normal. Unfortunately, because of optic nerve damage by glaucoma and radiotherapy, the right eye went blind.

COMMENT

In most cases of signet ring cell carcinoma described in the literature, upper and lower lids of one eye were involved.1-4 Three patients were initially treated by excision alone, all of them had a period of survival of at least 6 years. One of these patients...
developed a recurrence after 10 years, with preauricular lymph node metastasis, as a result of which he was treated with radiotherapy (50 Gy). He had at least 18 months of remission thereafter, but showed subclinical liver metastasis at necropsy; his death was not tumour related. Another patient was found to have pulmonary metastases from which he finally died.

Radiotherapy alone (35 Gy), as in our case, was applied to another patient. He showed infiltration of the lids and the anterior orbit, and had at least 6 years of remission. The only patient treated by orbital exenteration, radiotherapy, and tamoxifen died as a result of liver and bone metastases within a period of less than 6 years after initial diagnosis. His pretreatment status, showing extensive orbital infiltration, was quite similar to that of the patient we are presenting here. From the cases reported in the literature, we conclude that this tumour possesses a low to intermediate grade of malignancy. To date, 14 months after radiotherapy, our patient still shows remission. Thus, for elderly patients with extensive infiltration of orbital and adnexal tissue by an eccrine sweat gland carcinoma, we consider this conservative treatment sufficient to achieve local control.

We thank Dr T Rudolph for providing clinical data, Dr T Wendelhak for contributing histological sections, and Professor Dr H Witschel and Dr J P Alexander for reading the manuscript.

Endonasal endoscopic dacryocystorhinostomy for dacryocystocele in a 4 month old infant

EDITOR,—Canalisation of the nasolacrimal apparatus usually occurs at the same time throughout its length. However, its distal end has been shown to be occluded by a membrane in 73% of otherwise normal stillborn fetuses at term.1

For typical dacryocystoceles, a regimen of warm compresses and massage, with regular ophthalmological review to check for the first signs of dacrocystitis, seems to be reasonable. Should dacrocystitis supervene, the child should be admitted to hospital for the intravenous administration of antibiotics and probing of the nasolacrimal apparatus. Should the dacryocystocele recur or epithora ensue, and repeated probing does not give the result, it may be necessary to intubate the nasolacrimal apparatus2 or perform a dacryocystorhinostomy.3 In 1893, Caldwell described the first case of an endonasal operative approach to the lacrimal system. This technique was later modified by West and supported by Mosher in 1921.4 In spite of these attempts, the external dacryocystorhinostomy (DCR)—the technique inaugurated by Tosti in 1904—was, for a long time, the most accepted procedure for lacrimal sac surgery. The reason for this was presumably limited transnasal visualisation caused by bleeding during endonasal dacryocystorhinostomy.5

In 1974, Johnston and Karthikeyan revived the endonasal approach.6 Heerman and Neues used a microscope for a transnasal approach to the lacrimal sac,7 whereas McDonough and Meiring were the first to advocate endonasal dacryocystorhinostomy (EEDCR), in 1989.8

Using new instrumentation and techniques for endonasal sinus surgery in general, many authors have proved that EEDCR can be performed with lower morbidity in adults and with success rates equal to those achieved with the traditional external approach.9–11

CASE REPORT

A 4 month old girl presented with huge recurrent abscesses in the left medial canthal region (Fig 1) and a huge epithora. Initially she was managed by conservative methods (warm compresses and massage over the swollen lacrimal sac), but the clinical appearance did not show any change. She underwent several incisions whenever the abscess severely exacerbated, threatening to perforate spontaneously. Attempts to probe the nasolacrimal canal were performed in the “silent” phases of the disease, but the probe did not pass deeper than the bottom of the lacrimal sac, suggesting the absence of the canal. Attempts to irrigate the lacrimal canals were not successful either. A lacrimal sac massage resulted in a certain amount of mucus bursting out from the lacrimal sac, suggesting the absence of the canal. The clinical appearance did not resolve spontaneously or after conservative treatment, we performed an endonasal endoscopic dacryocystorhinostomy. As far as we know, this was the youngest child ever operated by means of EEDCR. The small anatomical dimensions of the infant nose posed a technical challenge in performing EEDCR: during the use of Richard’s otological drill for bone removal, there was some difficulty in concomitant endoscopic visualisation and potential damage to the nasal mucosa from rotation of the drill shaft. We also performed a lacrimal opening of 6 mm with angled endoscopic biting forceps (the usual opening is about 6 mm) longer diameter.

The bone was drilled off and thinned out so that the lacrimal sac became visible (the removal of the underlying lacrimal bone is more easily performed posteriorly, where it is thinner, but is more safely performed anteriorly to avoid the possibility of orbital disruption). The endonasal analysis probe was inserted into the lacrimal canal and the sac itself, tenting it towards the nasal cavity. Then lacrimal sac marsupialisation was performed, using otological microsurgical scissors and punches, and a large amount of turbid tears mixed with mucopurulent discharge was obtained.

A 6 cm long nasal thin gauze ribbon package with antibiotic ointment was placed in the operated region for 3 days. After 5 days, there was no sign of dacryocystocele or dacryocystitis on the girl’s face (Fig 2). Eight months after the surgery, she is feeling fine.

COMMENT

Since, after 16 weeks of life, the nasolacrimal duct obstruction and dacryocystocele did not resolve spontaneously or after conservative treatment, we performed an endonasal endoscopic dacryocystorhinostomy. As far as we know, this was the youngest child ever operated by means of EEDCR. The small anatomical dimensions of the infant nose posed a technical challenge in performing EEDCR: during the use of Richard’s otological drill for bone removal, there was some difficulty in concomitant endoscopic visualisation and potential damage to the nasal mucosa from rotation of the drill shaft. We also performed a lacrimal opening of 6 mm with angled endoscopic biting forceps (the usual opening is about 6 mm) longer diameter.

In comparison with an external dacryocystorhinostomy, EEDCR avoids an external scar and offers very low morbidity in the immediate postoperative course. In spite of the technical problems, we think that

EBV, even in such a small infant, can be a good therapeutic choice in cases refractory to conservative treatment (warm compresses, massage, probing) because of its non-invasive performance and a very fast postoperative rehabilitation.

CASE REPORT
In 1997 a 32 year old homosexual man presented for the first time to the University Eye Hospital, Tübingen. For 4 weeks he had suffered from an acute retinal necrosis of the left eye. His right eye was not affected. The visual acuity of the left eye was 0.1. The anterior segment of the eye showed corneal precipitates but no cells in the anterior chamber. Owing to massive cell infiltration in the vitreous the lower part of the fundus was not visible. There was a large necrotic area with bleeding and occlusive vasculitis in the upper nasal periphery (Fig 1). The patient claimed to be healthy, apart from an EBV infection with pericarditis which had occurred when he was 17 years old. Tests for HIV and syphilis were repeatedly negative, also for Lyme disease, toxoplasmosis, hepatitis B, HSV, and VZV. There were increased titres for EBV-IgA (1:128), EBV-IgG (1:1512), EBV nuclear antigen, and EBV early antigen (1:64), a constellation typical for an acute EBV infection. After therapy with aciclovir 5 × 400 mg, prednisolone 60 mg, acetylsalicylaceide (200 mg), and prednisolone 60 mg, acetylsalicylaceide (200 mg), and topical prednisolone acetate the symptoms decreased. After 8 weeks his visual acuity increased up to 0.5 but dropped to 0.2 after 5 months as a result of vitreous haemorrhages because of neovascularisation. After clearance of the bleeding and peripheral laser coagulation the neovascularisations resolved. The fundus showed scars but no holes in the area of the necrotic retina (Fig 2). After 25 months the visual acuity was 0.2. The anterior parts showed mild cataracts. Vitreous cell infiltration still persisted and the central part of the fundus was not clearly seen. The patient showed an absolute central scotoma and atrophy of the optic nerve, without treatment.

COMMENT
The role of EBV in ocular diseases is still not clear, because approximately 95% of adults are positive for EBV antigen and only a few suffer from ocular disease. Previously described cases of “EBV retinitis” only described inflammation of the posterior pole without scaring, which is not typical for viral retinitis. Proving an acute EBV infection usually is done with increased EBV titres. Such a constellation was found in our patient. The titre decreased during the following 12 weeks suggesting that EBV might play a part in this man’s retinitis. The reported patient showed all criteria of the American Uveitis Society for ARN.1

However, it is not possible to rule out that other herpesviruses have caused the retinitis. This probably could only have been proved with a diagnostic vitrectomy or anterior chamber tap which was refused because of improvement with treatment. Serological findings showed no signs of other herpes infections.2

Intrascleral recurrence of uveal melanoma after transretinal “endoresection”

EDITOR.—Conservation of the eye and vision in patients with juxtapapillary choroidal melanoma is still a challenge. Both plaque radiotherapy3 and proton beam radiotherapy4 tend to cause optic neuropathy, which is associated with disc and iris neovascularisation, vitreous haemorrhage, and neovascular glaucoma. These complications can also occur after photocoagulation, which is less effective than radiotherapy at destroying the deeper parts of the tumour.1 Transcleral local resection of posterior tumours is especially difficult with tumours extending close to the optic disc and is associated with an increased incidence of local tumour recurrence.1 For these reasons, techniques have been developed for removing posterior choroidal melanomas transretinally,1 using standard vitrectomy equipment. In a previous report, eight out of 52 cases received secondary photocoagulation for possible tumour recurrence at the margins of the surgical coloboma and one eviscerated eye was found to have microscopic tumour deposits.

www.bjophthalmol.com
CASE REPORT

A 40 year old man presented with a 6 month history of photopsia. He was found to have a choroidal melanoma in the right eye and referred for conservative treatment. On examination, the vision was 6/4 with each eye. The tumour was pigmented and located inferiorly, extending to within two disc diameters of the fovea and optic disc margin (Fig. 1). Approximately 40% of the retina was detached. On ultrasonography, the tumour had basal dimensions of 12.0 mm by 11.7 mm and a thickness of 4.8 mm (Fig 2). The left eye was healthy. Full systemic assessment revealed no other disease.

In April 1995, the retina was flat with an epiretinal membrane covering the inferior margin of the coloboma and a fibrovascular scar partially obscuring the optic disc. It was decided that the silicone oil should be left in place because of the high risk of retinal detachment. When reviewed in February 1999, the vision was hand movements and there was band keratopathy, which precluded ophthalmoscopy. Enucleation was performed because it was not possible to screen the eye adequately for local tumour recurrence. At the time of surgery, an extracapsular tumour nodule was noted medial to the optic nerve. The tumour nodule measured approximately 8 mm by 6 mm.

Pathological examination showed the recurrent tumour to be of mixed, spindle, and epithelioid cell type. The tumour appeared to arise within the sclera because of the way in which it was encapsulated by the scleral lamellae. The presence of nerve tissue within the tumour suggested that the melanoma had entered the sclera along a channel for a ciliary nerve. Posteriorly, the tumour had broken through the sclera into the orbit.

COMMENT

To our knowledge, this is the first report of intrascleral recurrence of choroidal melanoma after transretinal endoresection. The tumour probably survived the surgery and photocoagulation because it had invaded a scleral channel adjacent to the optic nerve.

It is known that intrascleral tumour deposits can survive after photocoagulation or transscleral local resection of choroidal melanoma. In the present case, the adjunctive photocoagulation after completion of the tumour resection was either of insufficient power or was not applied to the area where the scleral invasion had taken place. A more effective method of eliminating residual intrascleral tumour would have been to administer adjunctive plaque radiotherapy, which is routine after transscleral local resection in some centres. In the present case, however, this would probably have caused optic neuropathy.

Further follow up studies are required to determine the incidence of intrascleral tumour recurrence after endoresection of choroidal melanoma.

Figure 1 Fundus photographs (A) preoperatively, showing an inferior choroidal melanoma extending close to optic disc and fovea, and (B) 2 months postoperatively, showing surgical coloboma.

Figure 2 Light micrographs of the enucleated eye. (A) Low power view showing intrascleral tumour recurrence close to optic disc and (B) high power view showing a ciliary nerve within the tumour.
and B-scan) showed an acoustically hollow, pedunculated mass in the ciliary body region measuring 10 mm in thickness. Ciliary body melanoma was diagnosed and the eye was enucleated.

Histopathological examination revealed a heavily pigmented multilobulated tumour arising from the pars plana (Fig 1B). The highly cellular tumour was composed of a mixture of spindle and epithelioid cells with a predominance of epithelioid cells. About 15–20% of the tumour was composed of melanophages within extensive areas of necrosis (Fig 2). No mitotic figures were identified. The cataractous lens was partially encased and dislocated by tumour. Parts of the iris, ciliary body, and choroid were heavily pigmented and dendritic melanocytes were observed within the sclera and on the episcleral surface, especially near the optic nerve. These findings were consistent with sector ocular melanocytosis. The histopathological diagnosis was ciliary body melanoma and sector ocular melanocytosis.

The patient has been followed for 10 years and has no evidence of local or systemic metastases.

COMMENT

Uveal melanoma is very rare in children and adolescents. Shields and associates reported that approximately 1% of all uveal melanoma patients are 20 years of age or younger at diagnosis. In no case has any of these young patients presented with leucocoria. Ciliary body melanoma in both children and adults is usually asymptomatic and can remain quiescent before it is recognised clinically. The most common presenting manifestations of ciliary body melanoma include dilated episcleral vessels in the quadrant of tumour, secondary hypotony or glaucoma, and subluxation of lens with visual aberration. Parts of the iris, ciliary body and choroid were heavily pigmented by tumour, secondary hypotony or glaucoma, and mild cataract. Therefore, leucocoria from cataract is an unusual presenting sign reflecting cataract, retinal detachment, ocular inflammation, or retinoblastoma. Cataract rarely develops in eyes with retinoblastoma. Spontaneous extrusion of ciliary body melanoma is an unusual presenting sign of an intraocular tumour in a child, especially ciliary body melanoma and we are unaware of any previous report of this occurrence.

One condition associated with the development of uveal melanoma is ocular melanocytosis. Ocular melanocytosis generally presents as excessive pigmentation in the subcutaneous periorbital skin, episclera, uvea, orbit, and meninges. The lifetime risk for uveal melanoma in a patient with ocular melanocytosis is approximately 0.25%. Verdaguer found that four of seven young patients under age 20 years with uveal melanoma had ocular melanocytosis. It is possible that sector melanocytosis may have predisposed to the development of melanoma in this case.

The prognosis for large uveal melanoma generally is poor. Barr and associates reported that the 15 year survival for posterior uveal melanoma in children and adolescents was 75%, suggesting that it does not differ from its adult counterparts. They showed that a large tumour size of 10 mm or greater and extraocular extension were poor prognostic features. Shields and associates also found that large tumour size was an important predictive factor of metastatic disease in children with uveal melanoma. Despite the large size of the tumour in our patient, no mitotic activity was found on histopathological examination. This may explain the continued survival of our patient.

In conclusion, we report a case of ciliary body melanoma in a 9 year old child who presented initially with a tumour induced unilaterale cataract. A unilateral cataract in a child deserves an evaluation for common and rare conditions such as ciliary body melanoma.

Spontaneous extrusion of subconjunctival cysticercus cellosae

EDITOR,—Cysticercus cellosae, the larval form of Taenia solium (tapeworm), often affects the human eye. Human infection occurs on eating raw or inadequately cooked infected pork, consuming food or water contaminated with faecal matter containing the ova, or as a result of autoinfection. Sommering first reported a case of ocular cisticercosis. The parasite’s most favoured site is the eye. In any case, the ocular involvement is often unusual. Cysticercosis is known as subconjunctival cysticercosis, in which case the larva of the lattice (trematode) is lying quiet under the conjunctiva. The larva of the lattice (trematode) is lying quiet under the conjunctiva. In the past, this was often overlooked, and the disease was labelled as “latent”. In recent years, however, cysticercosis of the conjunctiva has been recognised more frequently. The purpose of this study is to describe the clinical features of subconjunctival cysticercosis of the conjunctiva.

CASE REPORT

A young 7 year boy presented with redness and swelling in the right eye. General physical and systemic examination revealed no abnormality. The right eye had a smooth, pinkish, hemispherical, subconjunctival, cystic swelling of approximately 8–9 mm in size near the inner canthus (Fig 1). It was loosely adherent to the eyeball, non-reducible, and was mildly tender. The conjunctival vessels over and around it were mildly congested. The left eye was normal. An ultrasound of the right eye done with a waterbath revealed a subconjunctival cysticercus cellulosae.
turbid contents within the cyst. The eyeball with a central echogenic scolex and subconjunctival space have been reported. Since 1970 only six cases of spontaneous extrusion of cysticercus from subconjunctival tissue and extraocular muscles. The cysticercus in the present case was subconjunctival and there was spontaneous expulsion. Since 1970 only six cases of spontaneous extrusion of cysticercus from subconjunctival space have been reported. In the three cases reported by Bansal extrusion of subconjunctival cysticercus cellulosae. A case of cysticerosis presenting with persistent diplopia and spontaneous extrusion.

COMMENT

Cysticercosis has a global distribution particularly in countries where there is increased incidence of pork eating. Ocular dissemination of cysticercus cellulosae is well known and is evident from several reports in the literature. The most favoured site is the vitreous and subretinal space followed by subconjunctival tissue and extraocular muscles. The cysticercus in the present case was subconjunctival and there was spontaneous expulsion. Since 1970 only six cases of spontaneous extrusion of cysticercus from subconjunctival space have been reported. In the three cases reported by Bansal et al. the cyst was located within the medial rectus muscle in the first case, in the subconjunctival space in the second case, and in the superior orbit in the third case from where they were extruded. In the present case the cystic swelling was present near the inner canthus of the eye with attachment to the underlying muscle sheath.

In orbital and subconjunctival cysticercosis the cyst is usually attached to the muscle sheath, where it induces an inflammatory reaction and because of its constant motility it erodes through the conjunctiva and comes out leaving a rent in the conjunctiva which ultimately heals within a short period. This case report highlights the importance of ultrasound in such lesions and should be the primary mode of investigation. On ultrasound the cyst is seen as a sonolucent area with well defined anterior and posterior margin with the presence of a central echodense, curvilinear highly reflective structure within the cyst, that of a scolex.

Massive basal cell carcinoma in a schizophrenic patient: treatment options and constraints

EDITOR,—Basal cell carcinoma (BCC) is the most common malignant tumour of the eyelids and face. Factors which increase the chance of orbital invasion include a medial canthal location, slow indolent growth, morpheaform growth pattern, surgical recurrence, advanced presentation, and neglect. Orbital invasion predisposes to intracranial involvement by direct or perineural spread. Management of orbital invasion is difficult and requires a multidisciplinary team approach for radical surgery and/or radiotherapy.

We present a 76 year old Ukrainian man with a neglected tumour on his forehead which had spread over several years to involve the upper eyelids, anterior orbits, and ethmoid sinuses.

CASE REPORT

A 76 year old man with a long history of untreated forehead BCC complained of deteriorating vision in his right eye and ocular discharge. He had been admitted by the care of the elderly unit, for social reasons. He was a known paranoid schizophrenic treated with psychotropic drugs. Four years previously his physician had measured the lesion as being 2 cm × 4 cm and recommended plastic surgery, which was declined.

There was a massive, fungating lesion of the forehead, superior orbits, and nasal bridge, at least 15 cm × 17 cm (Fig 1). The right uncorrected visual acuity was 6/24 and left only light perception (unable to use a pin hole). There was fixed ptosis and right lower eyelid involuntarily ectropion. There was an opaque left cornea. The right fundus was normal. He did not permit intraocular pressure measurement.

In the three cases reported by Bansal extrusion of subconjunctival cysticercus cellulosae. A case of cysticerosis presenting with persistent diplopia and spontaneous extrusion.

Figure 1 A subconjunctival cyst at the inner canthus of the right eye.

Figure 2 Ultrasound showing a cystic mass in the subconjunctival region in the lateral aspect of the eyeball with a central echogenic scolex and turbid contents within the cyst.

Investigations included a computed tomograph (CT) scan to evaluate the extent of tumour invasion and an incisional biopsy for histopathological diagnosis. The CT scan showed extensive soft tissue destruction, loss of the nasal bone, frontal sinuses, and bilateral anterior ethmoid, and extracranial orbital invasion (Fig 2). Histopathology confirmed extensive solid basal cell carcinoma.

He received symptomatic care with lid cleansing and topical chloramphenicol. A low visual aid assessment was arranged. Palliative treatment with radiotherapy was recommended but he refused all treatment including the low vision assessment.

The patient underwent a thorough mental status examination, which confirmed well controlled schizophrenia. We were not empowered to detain him for treatment against his will. He discharged himself from hospital with an untreated fungating BCC.

COMMENT

This patient had a neglected BCC which had caused destruction of soft tissue and bone, with orbital invasion and was threatening the vision in his remaining eye.

Where advanced scalp cancer displays deep invasion, radical excision and reconstruction are indicated. Some authors suggest that aggressive surgical management of advanced skin neoplasia is the only treatment to produce long term survival. In malignant cutaneous tumours involving the anterior skull base, invasion of the dura mater significantly affects survival. In particular, spread along the medial orbital wall can lead to meningeval infiltration by direct invasion. As with squamous cell carcinoma, large basal cell carcinomas can invade the central nervous system by
perineural spread. Our patient risks spread of the tumour along the supraorbital and supra- 
trochlear nerves.

When local surgical therapy fails to prevent recurrence or definitive surgical resection is not possible, as in this case, alternative thera-
pies must be considered. Opinions vary on the roles and efficacy of radiation therapy and chemotheraphy for extensive lesions. Cisplatin and doxorubicin have been reported to achieve complete remission of recurrent invasive 
BCC of the medial canthus and orbit at 5 years. Using adjunctive radiotherapy, large BCCs of the head showed partial to complete 
response but no cures achieved. A complete

response but no cures achieved. A complete BCCs of the head showed partial to complete

response was defined as disappearance of all measurable lesions (but cancer cells are still present microscopically) and a partial re-

response was 50% reduction in all lesions.3

Patients with large or aggressive skin cancer are fortunately uncommon and management should be individualised following discussion 
with both the patient and his/her family. The options include a combination of surgery, radiotherapy, and chemotherapy with every 
effort made to preserve vision.

Our elderly, schizophrenic patient declined treatment and in these circumstances symp-
toms that can be offered. Legal 
issues prevent forced treatment.

Informed consent includes providing ade-
quate information about the treatment to 
make a reasoned decision. Obtaining consent
must be free of coercion or threats, which 
would affect the patient’s decision. The 
patient must be presumed competent unless 
shown otherwise. Psychiatric assessment con-
firmed that this patient was competent to 
make his own decisions. Exceptions include if immediate need is needed and the patient is unable to provide it (in coma or insufficient time to obtain it), the patient is legally incompetent to make a treatment decision, 
or decides to waive the right to be fully 
Informed. Untreated, the outlook for this patient is 
grim.

Spontaneous resolution of eyeball 
displacement caused by maxillary sinusitis

EDITOR,—Spontaneous displacement of the eyeball caused by maxillary sinusitis is rare 
but is well documented.1–3 Different treat-
ments have been suggested but all are surgical. Spontaneous enophthalmos due to 
maxillary sinusitis was first described by 
Montgomery‡; there have since been a series of 
reports describing this condition. The 
mechanism appears to arise from obstruction 
of the osteomeatal complex which impairs 
sinus ventilation. The resorption of retained 
secretions within the sinus produces a nega-
tive pressure which results in erosion of the 
thin orbital floor.4 In the absence of trauma 
the triad of obstructive sinus disease, diminu-
sed antral volume, and enophthalmos has 
been thought to be caused by inflammatory 
resorption and inferior displacement of 
the orbital floor.5 The globe is also 
displaced downwards and backwards such 
that the patient will have a narrow palpebral 
fissure and a deep superior sulcus above the 
eye.6

CASE REPORT
A 29 year old white male presented to the 
ophthalmology clinic having noticed that his 
right eye had been at a lower level than left 
one for the previous 2 years. There was no 
history of trauma. There were no nasal 
complaints or past history of sinusitis. On 
examination, the right globe was displaced 
inferiorly by 5–6 mm. Ophthalmic examina-
tion, including a visual acuity cover test and 
ocular movements were otherwise normal. 
A computed tomograph (CT) scan showed an 
opaque right maxillary antrum which was 
hypoplastic. The floor of the orbit was eroded 
and the right eyeball had sunk into the 
antrum (Fig 1).

He was seen in the ENT clinic and listed for 
an endoscopic middle meatal antrostomy and 
repair of the orbital floor. The patient changed 
his address and we were unable to contact 
him. Three years later, he contacted the ENT 
department to inquire about his appointment. 
We advised him that a further review might be 
beneficial. When reviewed the right eye was 
noted to be in a normal position. A repeat scan 
showed the same retinaculum which produced 
the displacement of the globe (Fig 2).

Figure 1 CT scan showing hypoplastic opaque 
right maxillary antrum, eroded right orbital 
floor, and sunken right eyeball.

Figure 2 CT scan of the same patient after 3 years which 
shows reossified right orbital floor 
which is at a higher level than previously.

COMMENT
In this case report the support of the orbital 
floor was presumably lost secondary to block-
age of osteomeatal complex and subsequent 
Inflammatory changes and/or pressure 
changes within the antrum. Previous reports have 
advocated the surgical reconstitution of the 
orbital floor at an early stage.1–4 Maxillary 
sinusitis is frequently a self resolving disease, 
as occurred in this case. Resolution of 
maxillary sinusitis, inflammatory and pressure 
components that produced the displacement 
of eyeball appears to have taken place. In 
the absence of negative pressure in the maxillary 
antrum and with orbital floor periosteum 
intact, new bone was laid down to reform the 
orbital floor with subsequent reposisioning of 
the globe.

This case raises the question as to whether 
surgical intervention is required in cases 
if the maxillary sinus disease can be treated or 
resolves of its own accord. Should medical or 
conservative management be inadequate then 
it can be hypothesised that a simple middle 
meatal antrostomy may be enough, following 
which the orbital floor might reform without 
need for reconstruction. The authors suggest 
this as a hypothesis extrapolating from the 
events that occurred in this patient.

Familial thrombophilia and normal tension glaucoma

EDITOR,—The aetiology of normal tension 
glaucoma (NTG) is still debatable. Abnormal 
blood flow, systemic hypertension, abnormal 
blood coagulability, and other factors associ- 
ated with cerebrovascular disease may have a 
causative role in NTG.1 A study was designed to 
look at the prevalence of familial thrombo-

philia in cases of NTG.

www.bjophthalmol.com

Letters
CASE REPORT

Seventy two patients were identified from ophthalmological database records with the diagnosis of NTG (defined as intraocular pressure < 21 mm Hg, open drainage angle on gonioscopy, absence of any secondary cause of glaucoma and typical optic disc cupping which correlates with the visual field defect). Strict criteria were used for entry into the study. Patients with NTG had to be under the age of 70 years with normal computerised tomography and normal day time intraocular pressure phasing. Forty five patients did not fulfil these criteria and so were excluded. Twenty seven patients formed the study group. None of these patients were on any medication which would be expected to have altered the values of the prothrombotic factors measured. The control group comprised 90 blood donors used by the regional thrombophilia laboratory as their control values of thrombophilic markers. The control group had an equal male:female ratio, an age range of 18–60 years, and no donor was on any medication or suffering from a medical illness. This gave a good control prevalence of the prothrombotic factors tested for in the study which are not altered by age variation. If any abnormality was found a repeat screen was performed to confirm the thrombophilic state. Blood for rheological factors (full blood count, plasma viscosity, lipid levels, glucose and liver function tests) and thrombophilic markers (protein S, protein C, factor V Leiden mutation, prothrombin G20210A allele, antiphospholipid antibodies, and hyperhomocysteinaemia) was taken for investigation. Informed consent was obtained and ethical approval had been given.

The study group was made up of 16 females and 11 males (ratio 1.5:1). The mean age of diagnosis was 60 years (range 43–69). Table I shows the patient details. Twenty three patients had a normal thrombophilia screen. Two patients had moderate hyperhomocysteinaemia (7% controls 8% p > 0.5). One was a smoker and had mild raised homocysteine (4% controls 3% p > 0.5). No patient had the prothrombin G20210A variant.

COMMENT

In trying to discover the aetiology of NTG, some studies have suggested that these patients may have altered rheology producing a greater tendency to thrombosis.1 7 There is also evidence of activation of the coagulation cascade and fibrinolytic pathway but there is no conclusive evidence of a general vascular aetiology in the causation of NTG.6 7

The factor V Leiden mutation is a common hereditary abnormality with a 1–4% prevalence of heterozygous carriers depending on geographic location and accounts for the majority of activated protein C resistance. It is known that familial thrombophilia greatly increases the risk of venous thrombosis but it must be stressed that the most people with the Leiden mutation will not experience a thrombotic event.7 10 The prothrombin G20210A variant is another common abnormality with a carrier prevalence of 1–4% being more common in southern Europe and, like the Leiden mutation, rare in people from Asian or African descent. This gave a good control prevalence of factor V Leiden in the patient and control groups, it and the non-significant prevalence of factor V Leiden in patient 23 did not have a causative role in her glaucoma though may have contributed to her deep vein thrombosis.

Retinal artery and vein occlusions have been documented with hyperhomocysteinaemia. A raised homocysteine level has many causes and the haematological and vascular abnormalities associated with hyperhomocysteinaemia lead to a prothromogenic and prothrombotic metabolic environment.6 Levels can be easily reduced with dietary folic acid supplementation, with or without vitamin B12, but it is unknown if this reduces the risk of vascular disease. It is also unknown if the strong link of hyperhomocysteinaemia and cardiovascular events is actually causal. Both patients in the study with hyperhomocysteinaemia were commenced on folic acid and subsequent levels of homocysteine were in the normal range.

Other hereditary thrombophilic conditions, such as protein C and protein S deficiency, and antiphospholipid antibodies have been reported in association with ocular vascular pathology and a combination of these factors may further increase the risk of hypercoagulability. The low levels of antithrombin and protein C as seen in patient 20, are thought not to be prothrombotic.

It is unlikely that familial thrombophilia plays a significant aetiological role with NTG as a larger study is needed to confirm our findings. On the available evidence, thrombophilia screening in patients with NTG is not indicated.

Vigabatrin is an effective drug for controlling chronic epilepsy and is taken more commonly in conjunction with additional antiepileptic drugs. There has been increasing subjective evidence that this drug may be associated with visual field defects.1 11 We report here the interesting results we found from wide field multifocal ERGs performed on a patient taking vigabatrin.

EDITOR—Vigabatrin is an effective drug for controlling chronic epilepsy and is taken more commonly in conjunction with additional antiepileptic drugs. There has been increasing subjective evidence that this drug may be associated with visual field defects.1 11 We report here the interesting results we found from wide field multifocal ERGs performed on a patient taking vigabatrin.

CASE REPORT

A 52 year old white man was referred to the eye clinic with a 6 month history of bumping into objects. His optician reported a bilateral inferior and nasal field defect. On examination his visual acuity was 6/6, N5 with correction, Ishihara 17/17 in each eye and intraocular pressures were 19 mm Hg. He had a full range of ocular movements and pupillary reactions were normal. There was a mild pallor to both optic discs.
In November 1999 he was referred for conventional electrophysiological investigations, including electro-oculogram (EOG), visual evoked cortical potentials (VECP), and electroretinograms (ERG). All tests were performed in accordance with current ISCEV international standards. Findings were similar to other reports in that VECPs were normal, his EOGs were deemed to be equivocal in that the Arden index was >1.7 but <1.9. There was a small reduction in cone and maximal responses of the left eye in comparison with the patients left eye in comparison with the area of visual loss. Normal retinal function to be constructed. Therefore, he returned to using vigabatrin. At the time of examination treatment included vigabatrin, carbamazepine, sodium valproate, and propranolol. Although the patient has been informed of the associated risk of visual field loss; he has elected to remain on vigabatrin treatment.

In Table 1, conventional electrophysiology findings have enabled topographical maps of retinal function to be constructed. Wide field (90 degree) multifocal stimulation of the retina was performed using a custom built system with a 61 hexagonal display digitally back projected onto a polysilicon screen. Multifocal electroretinograms were performed in June 2000, showed good correlation with visual fields in determining the area of visual loss. Normal retinal function was recorded in the central 40° of both eyes. However, a delay in implicit timings occurred with eccentricity; more importantly there were marked reductions in peripheral b-wave amplitudes which may be suggestive of retinal toxicity. These results were consistent in both eyes. Figure 1 depicts MFERG responses of the patients left eye in comparison with the left eye of a normal subject.

The wide field multifocal ERG technique is the only objective tool for assessing the effect of vigabatrin toxicity on the peripheral retina. Currently, a larger clinical study utilising this technique will help to answer many of the unresolved issues associated with this form of toxicity. This technique will help to answer many of the unresolved issues associated with this form of treatment.

Figure 1. Left eye wide field multifocal ERG results from patient taking vigabatrin shown against results from a normal patient with no ocular pathology. (A) Multifocal waveforms show reduction in peripheral field retinal function, note areas of reduced b-wave amplitudes. (B) Normal multifocal waveforms. (C, D) Topographical maps of retinal function. (E, F) Plan view topographical maps.
