Daily tonometric curves after cataract surgery

S Saccà, A Marletta, A Pascotto, S Barabino, M Rolando, R Giannetti, G Calabria

Abstract

Aim—To evaluate daily tonometric curves after cataract surgery in patients with cataract only and in patients with cataract and glaucoma.

Methods—108 patients scheduled for cataract surgery were randomly allocated to two groups: 57 patients with cataract only (normal) and 51 with cataract and primary open angle glaucoma (POAG). All patients underwent extracapsular cataract extraction (ECCE) (manual technique with long wound), phacoemulsification (automated technique with short wound), or nucleus capture (manual technique with short wound). Intraocular pressure (IOP) was measured by Goldmann tonometry in all patients every 2 hours for 12 hours before the operation and at 1 and 6 months postoperatively.

Results—79 patients completed the 6 month examination. ECCE resulted in greater reductions in IOP than the other procedures (ECCE: 27% and 36% in normal patients and those with POAG, respectively; nucleus capture: 20% and 31%, respectively; phacoemulsification: 19% and 22%, respectively). The fluctuations in IOP before and after surgery were not statistically significant.

Conclusion—Cataract surgery in normal patients reduces IOP but does not eliminate fluctuations which are directly proportional to the IOP value and result partly from circadian rhythms. This important finding might influence our approach to treatment of patients with glaucoma.

(Br J Ophthalmol 2001;85:24–29)

Independent of the technique used, cataract extraction surgery induces variations in intraocular pressure (IOP) in normal patients and in those with primary open angle glaucoma (POAG). Some investigators have measured increased IOP after cataract surgery or have not reported significant tonometric variations. Gimbel et al. found a reduction in IOP following phacoemulsification but there was a significant difference in the decrease in IOP between glaucomatous eyes treated by phacoemulsification with trabeculectomy and those treated by phacoemulsification alone. However, more recently other authors have recorded a significant reduction in IOP after cataract surgery without significant tonometric differences between patients with glaucoma who underwent cataract surgery alone and those who underwent combined cataract and glaucoma surgery. Thus, in patients with both cataract and glaucoma, surgeons must decide whether to treat only one condition or both.

The disparity in the results could result from the fact that the IOP is not stable but fluctuates daily in normal individuals and in those with POAG. These daily variations are also seen in patients receiving antiglaucomatous treatment.

We have attempted to confirm the daily variations in IOP following three cataract procedures—extracapsular cataract extraction (ECCE), phacoemulsification, or nucleus capture—in normal patients and in those with POAG.

Patients and methods

Approval for this study was given by the ethics board of the ophthalmologic division of neurologic sciences and vision department of Genoa University and all study patients gave written informed consent.

Between March 1997 and December 1998 108 consecutive patients (61 women, 47 men) with cataract aged 45–82 years were enrolled. Patients were divided into two groups: 57 normal patients with cataract only and 51 patients with POAG and cataract. One eye of each patient was included in the study. In patients with bilateral glaucoma treatment with β blocking drugs was suspended during the follow up period and either dorzolamide or latanoprost, or both, were administered to eliminate possible pharmacological effects on the study eye. Patients in the two groups were randomly assigned to surgery with ECCE, phacoemulsification, or nucleus capture.

The inclusion criteria for the normal patients were: visual acuity ≤25/50 (Snellen fraction); an open anterior chamber angle; no history of previous filtration surgery; pupil size ≥5 mm after dilatation; absence of pseudoexfoliation syndrome, diabetes, uveitis, systemic collagenopathy, and objective neurological signs; no history of use of systemic antihypertensive drugs; and no administration of corticosteroids or systemic or topical antiglaucomatous drugs during the follow up period and either dorzolamide or latanoprost, or both, were administered to eliminate possible pharmacological effects on the study eye. Patients in the two groups were randomly assigned to surgery with ECCE, phacoemulsification, or nucleus capture.

The disparity in the results could result from the fact that the IOP is not stable but fluctuates daily in normal individuals and in those with POAG. These daily variations are also seen in patients receiving antiglaucomatous treatment.

We have attempted to confirm the daily variations in IOP following three cataract procedures—extracapsular cataract extraction (ECCE), phacoemulsification, or nucleus capture—in normal patients and in those with POAG.
All patients underwent a complete ophthalmological examination preoperatively including slit lamp examination with and without pupil dilatation, gonioscopy, and ophthalmoscopy. IOP was measured by Goldmann tonometry every 2 hours between 08.00 hours and 20.00 hours and the results were plotted into a diurnal tonometric curve. All measurements were performed by two doctors, but the same doctor always performed the IOP measurements in the same patients. Diurnal tonometric curves were repeated 1 week (SD 4 days) before surgery (T0) and at 1 month (SD 7 days) (T1) and 6 months (SD 12 days) (T2) after surgery.

Patients who presented with an IOP of more than 23 mm Hg during the plotting of the second tonometric curve (T1) received topical dorzolamide three times daily; this treatment was suspended 30 days before plotting the diurnal tonometric curve 6 months after surgery (T2).

On the day of surgery all patients received short acting mydriatic agents: 0.5% tropicamide, phenylephrine 10%, and cyclopentolate 1% were used for pupilary dilatation and diclofenac to maintain mydriasis. Peribulbar anaesthesia was induced with lignocaine hydrochloride 2%, bupivacaine hydrochloride 0.75% with 1:200 000 adrenaline, and 150 IU hyaluronidase. All operations were performed by the authors (nucleus capture by SCS, phacoemulsification by MR, and ECCE by GC). All patients with POAG received a 100 ml intravenous drip of mannitol 1 hour before surgery.

During the operation a metallic blepharostat was used and the superior rectus muscle was not fixed with a suture.

**Surgical Procedures**

**ECCE**

A 15 mm fornix based conjunctival flap was created and wet field cautery was performed for haemostasis. A 12 mm scleral incision was made with a steel blade 2 mm posterior to the surgical limbus. The anterior chamber (AC) was entered at 10 o’clock with a 21 gauge needle. An anterior capsulotomy was done with the same needle under water infusion. The nucleus was rocked free in the posterior chamber and the incision was enlarged to 11 mm. The nucleus was removed using pressure at the 6 and 12 o’clock limbus positions. The incision was closed with 8-0 silk sutures. Manual irrigation/aspiration of cortical material was performed with a McIntyre cannula. A 6.5 mm polymethylmethacrylate (PMMA) intraocular lens (IOL) was inserted into the posterior chamber and fixed in the sulcus under an air bubble. Wounds were closed with a continuous 10-0 nylon monofilament suture.

**Phacoemulsification**

A 3.2 mm corneal tunnel was created using a steel keratome in an oblique diving entry position. The AC was maintained with sodium chondroitin 4.0% and sodium hyaluronate 3.0% (Viscoat, Alcon). A 5.0 mm circular continuous capsulorhexis was performed. After hydrodissection a phacoemulsification tip was used to remove the lens nucleus; residual cortical material was removed by irrigation and aspiration. When cortical aspiration was complete, the incision was enlarged using a 5.2 mm steel keratome. A 5.0 mm PMMA posterior chamber IOL was placed in the capsular bag. The viscoelastic was aspirated and the incision was closed with a single radial stitch.

**Nucleus Capture**

A rectilinear 5.2 mm, half thickness corneal incision was made with a disposable knife on the astigmatism axis. A 3.2 mm corneal tunnel was created with a precalibrated knife. The AC depth was maintained with sodium hyaluronate, a 6.0 mm capsulorhexis was created, and hydrodissection and hydrodelineation were performed. The nucleus was moved into the AC by injecting a viscoelastic between the nucleus and the epinucleus. Nucleus capture was performed after the tunnel was enlarged to 5.2 mm using a bimanual manoeuvre in which...
was aspirated from the AC and the tunnel was closed with one 10-0 nylon suture.

All patients received topical tobramycin and dexamethasone eye drops were prescribed five times daily for 2 weeks and three times daily for an additional 7 days.

STATISTICAL ANALYSIS

Statistical analysis was performed by AM. Using SPSS 6.0 software, the data were analysed by parametric descriptive and probabilistic statistics to define all study variables. To evaluate the homogeneity of the patient groups, the χ² test was performed at the threshold (p=0.05) after patients were divided into groups based on 5 year age intervals.

One way analysis of variation (ANOVA) with Scheffé's test was used to evaluate internal variations and to compare data from the normal and POAG groups before surgery (T₀) and at 1 month (T₁) and 6 months (T₂) postoperatively. ANOVA was also used to compare the effects of the three surgical procedures on IOP.

The percentage daily variation (Z score) was determined using the formula Z score = (x – <x>)/<x> where <x> is the daily mean.

Results

Seventy nine patients (40 women) aged 45–82 years underwent a follow up examination 6 months postoperatively (Table 1). Twenty nine patients did not complete the study: one died, two developed surgical complications, six took drugs not included in the protocol, and 20 did not undergo follow up examinations.

Our results showed that all cataract procedures resulted in decreased IOP levels in normal patients (Fig 1) and in patients with POAG (Fig 2). ECCE resulted in the greatest decrease in IOP. The tonometric differences at 1 and 6 months postoperatively were statistically significant (p<0.001) with all surgical techniques (Table 2).

The average decreases obtained 1 month after surgery with ECCE were 3.46 mm Hg in normal patients and 6.65 mm Hg in patients with POAG. In the subsequent months there was an additional decrease of almost 1 mm Hg which was not statistically significant. With phacoemulsification and nucleus capture the greatest decrease in IOP was seen after 6 months, but the decrease was not significant after the first month (Table 3).

When only the reduction in IOP was considered, ECCE was the most efficacious surgical technique and resulted in an average fall in IOP of 27% in normal patients and 36% in patients with POAG. Nucleus capture resulted in falls of 19% and 30%, respectively, and phacoemulsification in falls of 19% and 22%, respectively (Table 2). No significant difference was seen between phacoemulsification and nucleus capture but ECCE produced statistically significant differences at T₀ and T₂ compared with the other procedures (p=0.0427 and p=0.0260, respectively, one way ANOVA with Scheffé's test).

At the end of the follow up period three patients who underwent phacoemulsification

In both groups of patients the difference between the IOP values 1 month after surgery and 6 months after surgery was about 1 mm Hg (not statistically significant).

ECCE = extracapsular cataract extraction; phaco = phacoemulsification; NC = nucleus capture; POAG = primary open angle glaucoma.
and two who underwent nucleus capture had at least one IOP measurement higher than 21 mm Hg during the plotting of the daily tonometric curve. This study has provided a global picture of variations in IOP after cataract surgery and indicates that IOP levels fluctuate daily before and after surgery in all study patients (Table 4). The fluctuations were not statistically significant in either group before or after surgery, independent of the technique used. The daily fluctuations in IOP occurred generally in the same manner in the two patient groups: higher IOP values were found at 08.00 hours and lower values were found in the afternoon (Figs 1 and 2). In patients with POAG these fluctuations were reduced when the IOP levels were lower (Table 4).

Discussion
At the end of the follow up period 12.2% of the patients with POAG had IOP values above 21 mm Hg at least once during the plotting of the diurnal tonometric curve. In the remaining patients with POAG a reduction in IOP was observed 1 month postoperatively as in the normal patients.

It is noteworthy that IOP levels fluctuate, which makes plotting of accurate diurnal tonometric curves important. On the other hand, pressure peaks are reported to be important in determining the extent of glaucomatous damage.

In our study population one patient in the POAG group had an IOP of 24 mm Hg at 16.00 hours at the 1 month examination and 23 mm Hg at 16.00 hours at the 6 month examination. During the remainder of the day the tonometric measurements were all equal to or lower than 20 mm Hg (Fig 3). This case indicates that it can be difficult to obtain precise measurements in a patient with glaucoma. Furthermore, when the IOP decreased we also saw stabilisation of the curve in patients with POAG, which confirms that daily IOP fluctuations are directly proportional to the IOP level.

These fluctuations can be partly attributed to circadian rhythms, and our study confirmed that there were no statistically significant differences in IOP fluctuations before and after surgery in normal patients and in those with POAG. Furthermore, the curves observed in the two patient groups had a similar concave profile with higher values in the morning, decreasing in the afternoon and increasing again in the evening (Fig 4).

Based on these results, cataract extraction decreases the IOP level but does not eliminate the circadian rhythm. The exact mechanism by which cataract surgery improves IOP is unclear; many hypotheses have been presented in the literature (Fig 5), all based on three pathogenic mechanisms: hyposecretion, increase in prostaglandins, and increase in aqueous flow.

Cataract removal is associated with biochemical or blood-aqueous barrier changes; such changes have been shown to influence IOP levels. Phacoemulsification produces free radicals that may act as inflammatory agents.
