Daily tonometric curves after cataract surgery

S Saccà, A Marletta, A Pascotto, S Barabino, M Rolando, R Giannetti, G Calabria

Abstract

Aim—To evaluate daily tonometric curves after cataract surgery in patients with cataract only and in patients with cataract and glaucoma.

Methods—108 patients scheduled for cataract surgery were randomly allocated to two groups: 57 patients with cataract only (normal) and 51 with cataract and primary open angle glaucoma (POAG). All patients underwent extracapsular cataract extraction (ECCE) (manual technique with long wound), phacoemulsification (automated technique with short wound), or nucleus capture (manual technique with short wound). Intraocular pressure (IOP) was measured by Goldmann tonometry in all patients every 2 hours for 12 hours before the operation and at 1 and 6 months postoperatively.

Results—79 patients completed the 6 month examination. ECCE resulted in greater reductions in IOP than the other procedures (ECCE: 27% and 36% in normal patients and those with POAG, respectively; nucleus capture: 20% and 31%, respectively; phacoemulsification: 19% and 22%, respectively). The fluctuations in IOP before and after surgery were not statistically significant.

Conclusion—Cataract surgery in normal patients reduces IOP but does not eliminate fluctuations which are directly proportional to the IOP value and result partly from circadian rhythms. This important finding might influence our approach to treatment of patients with glaucoma.

(Br J Ophthalmol 2001;85:24–29)
The groups are homogeneous for age (p = not significant, \( \chi^2 \) test). POAG = primary open angle glaucoma. ECCE = extracapsular cataract extraction; phaco = phacoemulsification, NC = nucleus capture; \( H \) = sex.

All patients underwent a complete ophthalmological examination preoperatively including slit lamp examination with and without pupil dilatation, gonioscopy, and ophthalmoscopy. IOP was measured by Goldmann tonometry every 2 hours between 08.00 hours and 20.00 hours and the results were plotted into a diurnal tonometric curve. All measurements were performed by two doctors, but the same doctor always performed the IOP measurements in the same patients. Diurnal tonometric curves were repeated 1 week (SD 4 days) before surgery (T0) and at 1 month (SD 7 days) (T1) and 6 months (SD 12 days) (T2) after surgery.

Patients who presented with an IOP of more than 23 mm Hg during the plotting of the second tonometric curve (T1) received topical dorzolamide three times daily; this treatment was suspended 30 days before plotting the diurnal tonometric curve 6 months after surgery (T2).

On the day of surgery all patients received short acting mydriatic agents: 0.5% tropicamide, phenylephrine 10%, and cycloplegolate 1% were used for pupillary dilatation and diclofenac to maintain mydriasis. Peribulbar anaesthesia was induced with lignocaine hydrochloride 2%, bupivacaine hydrochloride 0.75% with 1:200 000 adrenaline, and 150 IU hyaluronidase. All operations were performed by the authors (nucleus capture by SCS, phacoemulsification by MR, and ECCE by GC). All patients with POAG received a 100 ml intravenous drip of mannitol 1 hour before surgery.

During the operation a metallic blepharostat was used and the superior rectus muscle was not fixed with a suture.

**Surgical procedures**

**ECCE**

A 15 mm fornix based conjunctival flap was created and wet field cautery was performed for haemostasis. A 12 mm scleral incision was made with a steel blade 2 mm posterior to the surgical limbus. The anterior chamber (AC) was entered at 10 o’clock with a 21 gauge needle. An anterior capsulotomy was done with the same needle under water infusion. The nucleus was rocked free in the posterior chamber and the incision was enlarged to 11 mm. The nucleus was removed using pressure at the 6 and 12 o’clock limbus positions. The incision was closed with 8-0 silk sutures. Manual irrigation/aspiration of cortical material was performed with a McIntyre cannula. A 6.5 mm polymethylmethacrylate (PMMA) intraocular lens (IOL) was inserted into the posterior chamber and fixed in the sulcus under an air bubble. Wounds were closed with a continuous 10-0 nylon monofilament suture.

**Phacoemulsification**

A 3.2 mm corneal tunnel was created using a steel keratome in an oblique diving entry position. The AC was maintained with sodium chondroitin 4.0% and sodium hyaluronate 3.0% (Viscoat, Alcon). A 5.0 mm circular continuous capsulorhexis was performed. After hydrodissection a phacoemulsification tip was used to remove the lens nucleus; residual cortical material was removed by irrigation and aspiration. When cortical aspiration was complete, the incision was enlarged using a 5.2 mm steel keratome. A 5.0 mm PMMA posterior chamber IOL was placed in the capsular bag. The viscoelastic was aspirated and the incision was closed with a single radial stitch.

**Nucleus capture**

A rectilinear 5.2 mm, half thickness corneal incision was made with a disposable knife on the astigmatism axis. A 3.2 mm corneal tunnel was created with a precalibrated knife. The AC depth was maintained with sodium hyaluronate, a 6.0 mm capsulorhexis was created, and hydrodissection and hydrodelineation were performed. The nucleus was moved into the AC by injecting a viscoelastic between the nucleus and the epinucleus. Nucleus capture was performed after the tunnel was enlarged to 5.2 mm using a bimanual manoeuvre in which...
All patients received topical tobramycin and dexamethasone eye drops were prescribed five times daily for 2 weeks and three times daily for an additional 7 days.

STATISTICAL ANALYSIS

Statistical analysis was performed by AM. Using spss 6.0 software, the data were analysed by parametric descriptive and probabilistic statistics to define all study variables. To evaluate the homogeneity of the patient groups, the χ² test was performed at the threshold (p=0.05) after patients were divided into groups based on 5 year age intervals.

One way analysis of variation (ANOVA) with Scheffe’s test was used to evaluate internal variations and to compare data from the normal and POAG groups before surgery (T₀) and at 1 month (T₁) and 6 months (T₂) postoperatively. ANOVA was also used to compare the effects of the three surgical procedures on IOP.

The percentage daily variation (Z score) was determined using the formula Z score = (x—<x>)/<x> where <x> is the daily mean.

Results

Seventy nine patients (40 women) aged 45–82 years underwent a follow up examination 6 months postoperatively (Table 1). Twenty nine patients did not complete the study: one died, two developed surgical complications, six took drugs not included in the protocol, and 20 did not undergo follow up examinations.

Our results showed that all cataract procedures resulted in decreased IOP levels in normal patients (Fig 1) and in patients with POAG (Fig 2). ECCE resulted in the greatest decrease in IOP. The tonometric differences at 1 and 6 months postoperatively were statistically significant (p<0.001) with all surgical techniques (Table 2).

The average decreases obtained 1 month after surgery with ECCE were 3.46 mm Hg in normal patients and 6.65 mm Hg in patients with POAG. In the subsequent months there was an additional decrease of almost 1 mm Hg which was not statistically significant. With phacoemulsification and nucleus capture the greatest decrease in IOP was seen after 6 months, but the decrease was not significant after the first month (Table 3). When only the reduction in IOP was considered, ECCE was the most efficacious surgical technique and resulted in an average fall in IOP of 27% in normal patients and 36% in patients with POAG. Nucleus capture resulted in falls of 19% and 30%, respectively, and phacoemulsification in falls of 19% and 22%, respectively (Table 3). No significant difference was seen between phacoemulsification and nucleus capture but ECCE produced statistically significant differences at T₁ and T₂ compared with the other procedures (p=0.0427 and p=0.0260, respectively, one way ANOVA with Scheffe’s test).

At the end of the follow up period three patients who underwent phacoemulsification...
and two who underwent nucleus capture had at least one IOP measurement higher than 21 mm Hg during the plotting of the daily tonometric curve.

This study has provided a global picture of variations in IOP after cataract surgery and indicates that IOP levels fluctuate daily before and after surgery in all study patients (Table 4). The fluctuations were not statistically significant in either group before or after surgery, independent of the technique used. The daily fluctuations in IOP occurred generally in the same manner in the two patient groups: higher IOP values were found at 08.00 hours and lower values were found in the afternoon (Figs 1 and 2). In patients with POAG these fluctuations were reduced when the IOP levels were lower (Table 4).

**Discussion**

At the end of the follow up period 12.2% of the patients with POAG had IOP values above 21 mm Hg at least once during the plotting of the diurnal tonometric curve. In the remaining patients with POAG a reduction in IOP was observed 1 month postoperatively as in the normal patients.

It is noteworthy that IOP levels fluctuate, which makes plotting of accurate diurnal tonometric curves important. On the other hand, pressure peaks are reported to be important in determining the extent of glaucomatous damage.

In our study population one patient in the POAG group had an IOP of 24 mm Hg at 16.00 hours at the 1 month examination and 23 mm Hg at 16.00 hours at the 6 month examination. During the remainder of the day the tonometric measurements were all equal to or lower than 20 mm Hg (Fig 3). This case indicates that it can be difficult to obtain precise measurements in a patient with glaucoma. Furthermore, when the IOP decreased we also saw stabilisation of the curve in patients with POAG, which confirms that daily IOP fluctuations are directly proportional to the IOP level.

These fluctuations can be partly attributed to circadian rhythms, and our study confirmed that there were no statistically significant differences in IOP fluctuations before and after surgery in normal patients and in those with POAG. Furthermore, the curves observed in the two patient groups had a similar concave profile with higher values in the morning, decreasing in the afternoon and increasing again in the evening (Fig 4).

Based on these results, cataract extraction decreases the IOP level but does not eliminate the circadian rhythm. The exact mechanism by which cataract surgery improves IOP is unclear; many hypotheses have been presented in the literature (Fig 5), all based on three pathogenic mechanisms: hyposecretion, increase in prostaglandins, and increase in aqueous flow.

Cataract removal is associated with biochemical or blood-aqueous barrier changes; such changes have been shown to influence IOP levels. Phacoemulsification produces free radicals that may act as inflammatory Table 4 Intraocular pressure fluctuations in normal patients and patients with primary open angle glaucoma (POAG) treated with the three surgical procedures

The differences were not statistically different.

ECCE = extracapsular cataract extraction; phaco = phacoemulsification; NC = nucleus capture; $T_0$ = before surgery; $T_1$ = 1 month after surgery; $T_2$ = 6 months after surgery.

![Figure 3](image-url) Intracocular pressure (IOP) in the left eye of an 82 year old woman with primary open angle glaucoma of almost 10 years’ duration preoperatively ($T_0$), 34 days after phacoemulsification ($T_1$), and at the end of follow up ($T_2$). Tonometric decompensation is evident only at 16.00 hours.

![Figure 4](image-url) Mean intraocular pressure (IOP) in (A) normal patients and (B) patients with primary open angle glaucoma before surgery ($T_0$) and at 1 month ($T_1$) and 6 months ($T_2$) postoperatively. The IOP values have a concave profile which confirms circadian rhythms. IOP fluctuations at the end of the follow up period are always present, even though the ranges decrease as in the group with primary open angle glaucoma. ECCE = extracapsular cataract extraction; phaco = phacoemulsification; NC = nucleus capture.
Ciliary

- Suppressive effect on ciliary body function
- Partial ciliary body detachment
- Ciliary body irritation

Biochemical

- Aqueous humour changes
- Increasing permeability of the blood-aqueous barrier

IOL release

- IOL position
- Traction on ciliary body
- Chronic inflammation
- IOL thickness
- Trabecular space widening
- Schlemm breakdown prevention

Morphological

- Increase in anterior chamber
- Space enlargement

Surgery procedure related

- Small corneal incision
- Washing out effect on trabecular meshwork
- Capsulorhexis size
- Clear corneal incision

**Figure 5  Factors that induce reduction in intraocular pressure (IOP) after cataract surgery. The various hypotheses focus on three principal factors that can cause an increase in aqueous flow with increased release of endogenous prostaglandins. IOL = intraocular lens.**

**Hyposcretion of aqueous humour**

- **Prostaglandins**
- **IOP increase**

Improved outflow facility

Mediators causing breakdown of the blood-aqueous barrier, ECCE, a manual surgical technique that requires a long surgical wound, activates phospholipase A₂ and liberates arachidonic acid which is followed by local production of prostaglandins, thromboxane, prostacyclin, and leukotriene, even when there is minimal surgical trauma. Nucleus capture is also a manual surgical technique but the wound is shorter, similar to that made during phacoemulsification, and the functional results are similar.

To our knowledge there have been no reports of biochemical modifications induced by manual surgical techniques with small wounds, such as in nucleus capture, but clinical trials have indicated that less postoperative infection is induced by phacoemulsification than by ECCE.

IOL implantation in the capsular bag causes less inflammation and postoperative cataract formation than sulcus fixation of IOLs, and creation of a large capsulorhexis does not affect the total amount of postoperative cataract formation but may enhance the inflammatory response. Furthermore, the presence of an IOL in the sulcus may irritate the iris and ciliary body, which have great potential for prostaglandin synthesis. Other studies have suggested that synthesis of prostaglandins and cytokines may also be related to the wound healing process and proliferation of lens epithelial cells postoperatively. In any event, prostaglandin release is greater with ECCE than with phacoemulsification. In particular, the exogenous prostaglandin PGF₂α and its analogues stimulate the formation of PGE₂, PGD₂, and PGF₂α, in the iris and ciliary muscle which interact with the prostaglandin receptor to stimulate phospholipase A₂ and release amino acids for prostaglandin synthesis. Relaxation of ciliary muscles by PGF₂α and its analogues via release of endogenous PGE₂, a potent activator of the adenylate cyclase system, could partly explain how these prostaglandins may increase uveoscleral outflow and consequently lower IOP.

Meyer et al have shown that in phacoemulsification the flow coefficient of aqueous humour remains raised compared with the preoperative values. We believe that postoperative inflammation and subsequent prostaglandin release have a central role in decreasing IOP which could be the result of increased uveoscleral flow after an increase in endogenous postoperative prostaglandin synthesis (Fig 3), which confirms the results of Kerstetter et al.

In our opinion, surgical techniques that require short wounds induce less inflammation and less prostaglandin release than techniques requiring longer wounds. However, manual techniques stimulate greater endogenous synthesis of prostaglandins, causing a more significant reduction in IOP.

In conclusion, cataract surgery induces tonometric compensation in more than 80% of patients with POAG with an IOP under 26 mm Hg and results in a reduction in the pharmacological doses used preoperatively. Even though follow up in the present study was limited to 6 months, IOP reductions have been seen up to 7 years after cataract surgery. The choice of the surgical technique is dependent on the surgeon, but the decrease in IOP is probably related to subclinical inflammation. Our work suggests that combined procedures should be used in eyes that are at risk of further damage to the optic nerve or in those with significant optic nerve damage and visual field loss. Those patients who do not have profound optic nerve damage and visual field loss might benefit from clear corneal cataract surgery alone. Further studies are needed to expand our knowledge concerning the safe approach to cataract surgery in patients with glaucoma. Finally, we emphasise the importance of diurnal tonometric curves which may contribute to greater control of IOP in these patients.

The authors have no proprietary interest in any aspect of this report.
