Corneal deposits after the topical use of ofloxacin in two children with vernal keratoconjunctivitis

Topical fluoroquinolones are broad spectrum, bactericidal agents with activity against both Gram positive and Gram negative corneal pathogens. Single drug administration with topical fluoroquinolones has been effectively used in treatment of bacterial ulcerative keratitis. The drugs are safe, but a white crystalline deposit, that in most cases spontaneously dissolved, has been reported with ciprofloxacin 0.3% and norfloxacin 0.3%. Up to now this side effect has not been described with ofloxacin 0.3%. We present two children with severe vernal conjunctivitis who developed corneal deposits after use of ofloxacin 0.3% eye drops.

Material and methods

Patient 1
A 6 year old boy with vernal keratoconjunctivitis (VKC) developed a painful right eye while on holiday. His ophthalmologist diagnosed a corneal ulcer and prescribed ofloxacin eye drops followed by ofloxacin ointment four times a day for 3 weeks, associated with prednislone drops. As the inflammation in the right eye persisted, the child was referred to our department. Slit lamp examination revealed mild VKC and a corneal ulcer with a dense, white, sharply demarcated crystalline deposit (Fig 1). All topical treatment was discontinued, but the side effect had not spontaneously disappeared. Twelve days after the discontinuation of the topical treatment a corneal scraping of the deposit was performed in combination with a sub-tarsal injection of corticosteroids in both eyes.

Results
The corneal scraping was analysed by microscopy. To that end, pefloxacin was added as internal standard and the minute tissue sample was extracted with an acid (formic acid, pH 3.0) mixture of water/acetoneitritile (60/40). An aliquot was injected onto a 1 mm × 15 cm fused silica ODS C18 column (5 µm), eluted isocratically (40 % acetonitrile) and full scan product ion spectrum (major diagnostic ions m/z 362.1, 318.1, and 264.1) unequivocally disclosed that ofloxacin was present in the deposit. After removal of the deposit the ulcer epithelialised rapidly.

Comment
Topical ofloxacin 0.3% has been used in the treatment of patients with bacterial keratitis, in an animal model of keratitis, and has been tested in an in vitro tear model. So far no reports of corneal deposits have been made. There is only one case report in which deposits of topical norfloxacin in the treatment of bacterial keratitis have been described. The presence of ofloxacin while treatment had ceased was confirmed by confocal microscopic analysis of ciprofloxacin and ofloxacin, however, the authors attributed the deposit to the use of ciprofloxacin, although they did not conduct an analysis on the corneal deposits.

We report for the first time two children who demonstrate corneal deposits of ofloxacin adherent to a corneal erosion caused by VKC. Analysis of a corneal deposit proved the presence of ofloxacin while treatment had been discontinued for 7 days, indicative of ofloxacin depot formation by precipitation.

The exact factors contributing to the formation of the fluoroquinolone precipitate are unknown, but pH solubility profiles are of importance. Ofloxacin, like the other fluoroquinolones, exhibits pH dependent solubility. In the in vitro tear model tear drug concentration of ofloxacin remained below solubility at all pH values tested (pH 6.4–7.2).

One could argue that VKC associated ulcers occur in a different “microenvironment” compared to bacterial ulcers. Mast cell activation leads to the release of different mediators and inflammatory cells, such as histamine, serotonin, heparin, prostaglandins, protease, tryptase and eosinophils, all of which can contribute to a “microenvironment” potentially promoting ofloxacin precipitation in one way or the other. It would be interesting to find out whether there are significant changes, pH or other, in the tears of children with VKC.

In conclusion, we can say that ofloxacin does not seem to form corneal deposits when used in the treatment of bacterial ulcers, contrary to ciprofloxacin or norfloxacin. However, clinicians should be aware that deposits can occur after the use of ofloxacin in VKC associated ulcers.

Chromosomal translocation in a family with ocular anomalies: indications for karyotype analysis

Hereditary isolated congenital malformations such as congenital cataracts or anterior segment anomalies are usually considered to be the result of a single gene mutation. The identification of associated abnormalities—dysmorphic features, a malformation in another organ system, or mental handicap, help to identify those who carry more severe genetic defects such as chromosome rearrangements. We describe a family where two otherwise healthy men, a father and son, had juvenile cataracts. They both had offspring with more severe ocular anomalies including anterior segment dysgenesis, as well as mental retardation and dysmorphic features. Recent karyotype analysis revealed a balanced.

Figure 1 Slit lamp detail of vernal keratoconjunctivitis associated ulcer with a white sharply demarcated ofloxacin deposit.
translocation in both father and son and a derived unbalanced translocation in their more severely affected children. Analysis of the translocation breakpoints led to the identification of a new human disease gene, MAF, in lens and anterior segment development.

Critically, for the family, the finding of the translocation provides an explanation for the severe ocular and other anomalies in the individuals with the unbalanced derivative karyotype. In addition, it allows the option of prenatal diagnosis for future offspring for individuals carrying the balanced translocation.

Family report

A man with juvenile onset cataracts, and a family history of this, sought genetic advice with his partner. This man (II.3, Fig 1) was the father of three children with ocular anomalies and developmental delay. He had juvenile onset, progressive cataracts which were removed at the age of 24 years. The cataracts resulted in widespread photophobia, with anterior and posterior sutural densities. General and other ocular examination was normal. This couple’s only living child, a daughter age 5 years (III.3, Fig 1), had been noted at birth to have opaque corneas, small lens remnants in each eye, and very flat anterior chambers with rims of abnormal iris tissue. Bilateral microphthalmia was present with axial lengths of 12 mm. Fundal examination and an ERG were normal. Bilateral corneal grafts were attempted, but rejection occurred. This child had significant developmental delay with learning and motor difficulties, saying approximately five single words and only just walking at the age of 5 years. She had microcephaly and dysmorphic features (Fig 2A and B).

Two previous siblings, now dead, had also had ocular and other anomalies. The elder of these (III.1, Fig 1) had unilateral cataract, global developmental delay, and similar facial features to III.3 (Fig 2C). She died age 6 years as a result of aspiration pneumonia. The other sibling (III.2, Fig 1) had cloudy corneas at birth. She died soon after birth as a result of laryngeal stenosis (Fig 2D).

Analysis of the family history revealed that the patient’s father (I.1, Fig 1), had another had juvenile onset cataracts but was otherwise well. He had two other children with ocular anomalies and mental impairment. The elder daughter (III.1, Fig 1) had juvenile onset cataracts and died age 29 years because of cardiac arrhythmia. The second daughter (III.2, Fig 1), developed cataracts in early childhood and had bilateral dense cataracts at the age of 30 years. Both these individuals had limited speech and required assistance with personal care. These women have dysmorphic facial features similar to those seen in their developmentally delayed nieces.

Karyotype analyses were requested on surviving family members. These demonstrated that the two otherwise normal men (I.1 and II.3), with juvenile onset cataracts, were carriers of the same balanced translocation 46,XY,der(5)(U;16)(p15.3;q23.2) (Fig 1). Their two surviving offspring (II.2 and III.3) have more severe ocular anomalies, mental retardation, and dysmorphic facial features both had the same balanced translocation karyotypes, 46,XX,der(5)(U;16)(p15.3;q23.2) (Fig 1). Tissue had been taken at necropsy for a karyotype analysis on III.2 which had also shown additional material on chromosome 5. This would be consistent with the unbalanced karyotype seen in her sibling, but unfortunately contact with the family about this at the time did not proceed. Karyotype analyses were not performed in II.1 or III.1 before their deaths and had not been performed in III.3 before the genetic referral.

Comment

The diagnosis of the chromosomal translocation has significant implications for management and options for individuals in this family. The indications for karyotype analysis are not specifically emphasised to ophthalmologists as this is generally not part of the ophthalmologist’s role in patient care. Nevertheless, chromosomal anomalies are frequently reported in the ophthalmic literature and contributions to identification of several genes in human eye disease, including PAX6, FOXC1, PITX2, and MAF from this family, have been made through analysis of chromosome abnormalities.

In assessing the child with a congenital ocular anomaly, the presence of at least one other anomaly including another malformation or mental retardation, with or without dysmorphic features, is an indication for karyotype analysis. For the child, the finding of a chromosomal abnormality identifies the likely underlying cause, gives information regarding prognosis and directs management options. For the family, the origin of the chromosomal abnormality is critical in determining the likelihood of recurrence in a future pregnancy.

The parents of a child with a chromosome abnormality should be offered karyotype analysis. If one of the parents is a carrier of a balanced form of the translocation, this carries a risk of recurrence of up to 20% or sometimes higher of having a malformed and mentally retarded child as a result of transmission of an unbalanced chromosomal complement. Couples where one partner is a balanced translocation carrier can be offered prenatal diagnosis in a future pregnancy. If a parent is a balanced translocation carrier, one of his or her parents may also be a carrier so that siblings and other more distant relatives may also carry the translocation with its attendant risks for a future pregnancy. If the parental karyotypes are normal, the chromosomal abnormality has probably arisen as a de novo event in the egg or sperm that went to make that child, and the likelihood of recurrence in a future pregnancy is low. Such risk analyses vary between families depending on family history and the particular chromosomal rearrangement: referral to a clinical genetics unit for assessment is recommended.

When a patient is seen with an ocular abnormality associated with mental retardation, dysmorphic features, or another malformation, a request or referral for karyotype analysis is indicated because of the significant

Figure 1 Pedigree and clinical features of translocation family. Individuals with the balanced translocation (B) have cataract alone, while those with the unbalanced derivative karyotype (U) have additional features including other ocular anomalies, mental retardation, dysmorphic features, and other malformations. In individuals with the balanced translocation (B), 46,XY,t(5;16)(p15.3;q23.2), telomeric portions of 5p and 16q are translocated with no obvious loss of chromosomal material. Individuals with the unbalanced translocation (U), 46,XX,der(5),t(5;16)(p15.3;q23.2), have inherited the derived chromosome 5 derivative (der(5)) from their father as well as his normal chromosome 16 and their mother’s normal 16, so they are trisomic for the telomeric portion of 16q containing MAF and monosomic for a small telomeric portion of 5p. NK = not known.
Topiramate induced myopic shift and angle closure glaucoma

Topiramate (Topamax; Ortho-McNeil Pharmaceutical, Raritan, NJ, USA) is an oral sulfa
drugs for the treatment of seizures. We report two cases of topiramate-induced uve
effusions. In one case, prompt discontinuation of topiramate prevented bilateral an
gle closure glaucoma. To our knowledge, case 1 is the first case in the ophthalmic
literature describing myopic shift without glaucoma.

Case 1

A 42 year old woman presented with a complaint of 1 day of blurry vision. Her me
surgical history was notable for hypertension and seizures. She had never worn glasses. Medica
tions included hydrochlorothiazide, Depakote, and Flovent. Topamax was started 2.5 weeks be
fore examination which revealed 20/200 in both eyes without correction (20/20 both eyes
with −4.00−0.75 × 76 right eye −4.00−1.00 × 90 left eye). Pupils and pressures were normal.
Anterior chambers were shallow, and gonioscopy revealed angles open to posterior
trabecular meshwork in both eyes. Cup-disc ratios were 0.3 in both eyes. Ultrasound
revealed uveal effusions (Fig. 1A and 2A). Topamax was stopped. By day 3, the uveal
effusions had decreased (Fig. 1B and 2B). By 1 week, she was able to see 20/20 (plano in both
eyes). Chambers were now open to ciliary body in both eyes.

Case 2

A 50 year old woman presented with a complaint of 3 days of blurry vision. Her me
surgical history was notable for uterine cancer, hypertension, asthma, depression, and morbid obesity. Drugs included Prozac, Vioxx, Zestril, and Flovent. Topamax was started 2 weeks earlier for weight loss. She saw 20/30 in both eyes with her glasses (+2.00 right eye +2.50 left eye). Pressures were 60 mm Hg in both eyes. Pupils were barely reactive without APD. Anterior chambers were shallow with
ciliary body in both eyes. Chambers were now open to ciliary body in both eyes.

features include thin upper lip, short nose, microcephaly, brachycephaly, coarse hair, small
hands with clinodactyly of second, fourth and fifth fingers. (C) III.1, similar facial features to
III.3. (D) III.2, infant dead as a result of laryngeal stenosis. Facial features include thin upper
lip and featureless philtrum.

impact that the diagnosis of a chromosomal abnormality has for the individual and family. In
this family the diagnosis of a familial chromosomal abnormality was made only re
cently. Before this five children were born over a period of 35 years with ocular abnormalities
and associated features including mental retardation, dysmorphic features, and other non
ocular malformation, all caused by a chromosome abnormality derived from the balanced translocation in their parent.

Maximal medications, laser iridotomy was performed in her right eye. She had stopped topiramate 1 day before presentation. On the second day, pressures were normal and B scan confirmed uveal effusions. By day 3, her vision was 20/20 in both eyes, and her pressures were normal on brimonidine 0.2% in both eyes. Gonioscopy revealed posterior trabecular meshwork right eye and no angle structures left eye (anterior chamber depths 2.69 mm right eye, 2.20 mm left eye). After 1.5 weeks, pressures were normal without medications. Angles were open to scleral spur in both eyes. Anterior chamber depths were 2.87 mm in both eyes. No uveal effusions were seen.

Comment

Drug induced myopia has been associated with sulfa drugs such as acetazolamide,1 sulfamethoxazole/trimethoprim,1 indapamide, promethazene, spironolactone, isosorbide dinitrate, and bromocriptine.2 Other drugs include tetracycline,3 corticosteroids, hydrochlorothiazide, penicillamine, quinine, metosorbide, isosorbide mononitrate, and aspirin.4 Recently, bilateral angle closure glaucoma with uveal effusions have been associated with topiramate.5,6

Although the mechanism for topiramate induced myopia is unknown, it may partly be from topiramate’s weak carbonic anhydrase inhibitor activity or a prostaglandin mediated effect.4 Since rechallenging at lower doses does not cause recurrence of myopia,5 allergic hypersensitivity is unlikely. Uveal effusions with ciliary body swelling cause forward rotation of the lens-iris diaphragm, causing myopia and angle closure glaucoma.

Including the three other cases in the ophthalmic literature which reported angle closure glaucoma,7–9 all were women between ages 34 and 53. The onset of high pressures varied from 1 day to 2.5 weeks.8 Angle closure glaucoma has been noted in a 5 year old (Clark T, personal communication, 19 April 2002). Although peripheral iridotomy may relieve some pupillary block (as suggested by case 2), most glaucoma cases resolve without miotics or iridotomy. Patients who develop blurred vision should promptly discontinue topiramate to prevent progression to angle closure.

LASIK induced choroidal infarcts

Laser in situ keratomileusis (LASIK) is now commonly used for correction of refractive error. Anterior segment complications relating to flap occurs occasionally.10 However, posterior segment complications are rare.11 Choroidal infarct following LASIK, to our knowledge, has never been reported. Here we report a case of bilateral choroidal infarct following a routine LASIK procedure.

Case report

A 23 years old woman underwent a LASIK excimer procedure to both eyes for correction of hypermetropia. Her preoperative refractive errors were right eye +5.00 and left eye +3.75, improving vision to 6/6 in the right eye and 6/5 in the left eye. However, the axial length was not measured. She had no other ocular pathology. The anterior segments and the fundi were normal. She was generally healthy and her blood pressure was 120/76 mm Hg. Her routine blood tests and chest x ray were within normal limits. She did not have any history of thrombophlebitic phenomena, therefore a routine thrombophilia screening test was not performed.

An uncomplicated routine LASIK procedure was performed on 31 August 2001 in both eyes. The keratome used was Hansatome. Postoperatively, she complained of reduced and wavy vision, with floaters in both eyes. However, 2 months later (3 November 2001) she had been referred to one us (RBJ). On examination now her vision was 6/18 with +1.0 D sph; +1.75D cyl @ 75° and 6/18, with –1.25 D sph; +1.50 D cyl @ 70° in right and left eye respectively. There were normal LASIK scars and no corneal staining. The intraocular pressure (IOP) was 20 mm Hg in both eyes. The anterior chambers were quiet and pupils reacted normally. The retinal examination showed multiple yellow-grey deep retinal lesions at posterior poles in both eyes. In each eye, there was at least one larger triangular shaped lesion measuring approximately 2 x 3 disc diameters in size temporal to the macula. There were several smaller satellite lesions around the macula, which were somewhat polygonal in shape. These lesions had sharp, well defined borders with a mild degree of retinal oedema. It should be noted that the lesions were almost symmetrical in each eye. The discs and blood vessels appeared normal. Fluorescein angiography showed normal transit of dye through the discs and blood vessels. The arteriovenous phase in each eye showed two typical triangular hyperfluorescent areas with apex pointing posteriorly. The smaller polygonal lesions showed punctate hyperfluorescence. The intensity of hyperfluorescence increased with the concentration of circulating dye during the transit and faded away towards the later phases of the angiography. The lesions were situated at a deeper level in comparison with the retinal blood vessels. The late phase in both eyes showed generalised staining of all lesions (Fig 1).

Figure 1  (A) The arteriovenous phase of the fluorescein angiogram of the right eye shows two punctate hyperfluorescent triangular lesions with apex pointing towards the posterior pole on the temporal side of the macula. There are several smaller lesions above and below the macula.  (B) The late venous phase of the fluorescein angiogram of the left eye done at the same session shows a large palquoid lesion on the temporal side of the macula with increased hyperfluorescence due to staining of the lesion.
The patient was treated with 60 mg of oral prednisolone in two divided dosage for 3 weeks which was then reduced to 20 mg twice daily. She was reviewed fortnightly. She was also given flurbiprofen sodium 0.05% as local anti-inflammatory drops to both eyes three times daily for 4 weeks.

After 6 weeks the retinal oedema settled with visible fine peppy pigmentation over the lesions. Fluorescein angiography was repeated which showed increased hyperfluorescence of all lesions during the transit with minimal staining towards the late phase. On her final review her visual acuities were right eye 6/9 with +1.0 D sph/+0.50 D cyl @ 180° and in left eye 6/6 with +0.50 D sph @ 180°. The IOP was 18 mm Hg in each eye. The anterior chambers were quiet. The fundi showed well defined fine pigmented lesions. Subsequent pigment changes seen were due to changes in the overlying retinal lesions. Infarction of choriocapillaris lobules. Therefore it is possible that this patient must be susceptible to the effect of raised IOP. The rise of IOP may be an associated factor. Therefore it is possible that this patient must be susceptible to the effect of raised IOP.

A case of Boerhaave's syndrome associated with raised intraocular pressure

We would like to report a fatal case of post-emetic oesophageal perforation (Boerhaave's syndrome). The condition was attributed to nausea and retching caused by raised intraocular pressure (IOP). We believe the case highlights the importance of early diagnosis and management of such rare cases.

Case report

An 81 year old man presented with a painful right eye. He felt nauseated and was retching. On examination visual acuity was 6/36 pinhole 6/18 right eye and 6/12 pinhole 6/5 left eye. The right eye was mildly inflamed and pseudophakic as a result of recent surgery. Right IOP was 58 mm Hg. The left eye showed no abnormality. Past ocular history included complicated right cataract surgery requiring pars plana vitrectomy and removal of lens fragment 6 weeks previously. Five weeks later he developed an inferior retinal detachment which was repaired by further vitrectomy, cryotherapy, encircling band, and gas tamponade (SF6 20%). Following discharge he was admitted to hospital and treated with intravenous Maxolon, topical Alphagan and Trusopt. IOP was 33 mm Hg 5 hours later. Early the following morning he had one episode of blood stained vomitus following which he developed sudden retrosternal chest pain and dysphoria. GTN spray and Gaviscon did not alleviate his symptoms. On examination he was very distressed and unable to lie flat. Cardiovascular and respiratory examination demonstrated no new pathology. His blood pressure, ECG, and oxygen saturation were normal. Abdominal examination revealed general tenderness and guarding in all quadrants. Abdominal and chest x rays were unre- markable as was abdominal ultrasound. Urgent surgical and medical opinions were sought. At lunch time he developed further sudden severe dyspnoea and became confused. Blood gases revealed severe acidosis with reduced PaO2 and PaCO2. Physicians believed this was a mixed metabolic and respiratory acidosis induced by pulmonary thromboembolism. He was anticoagulated and transferred to the high dependency unit. Repeat chest x ray at 20:00 showed a right sided pneumothorax. A chest drain was inserted. The pleuritic fluid sample contained bile, Gram positive cocci, and Gram negative rods. The patient, who by now was in septic shock, was commenced on broad spectrum intravenous antibiotics. Emergency laparotomy confirmed oesophageal perforation. After discussion with his family no further intervention was deemed justifiable. Our patient died a few hours later.

Comment

Boerhaave syndrome is transmural perforation of the oesophagus to be distinguished from Mallory-Weiss syndrome, non-transmural oesophageal tear also associated with vomiting. It is the result of a sudden rise in intraluminal oesophageal pressure produced during vomiting. Pain is the most consistent symptom, present in 70–90% of patients, and is usually related to the site of disruption (Table 1). Chest x ray suggests the diagnosis in 90% of patients, but immediately after disruption the chest film may be normal. Pneumomediastinum, surgical emphysema, mediastinal widening, or a mediastinal air-fluid level must prompt investigation to rule out oesophageal perforation. Survival depends upon early recognition and appropriate surgical intervention. The overall mortality rate is approximately 35%. Surgical repair within 24 hours carries 70–75% chance of survival. This falls to 35–50% if surgery is delayed longer than 24 hours and to approximately 10% if delayed longer than 48 hours. Surgical intervention is the optimum management in most cases. This case highlights two very important points, firstly, the importance of adequate IOP control and associated nausea, secondly, although the above case is rare familiarity of the case and its inclusion in the differential diagnosis can be potentially life saving.

Severe bilateral necrotising retinitis caused by Toxoplasma gondii in a patient with systemic lupus erythematosus and diabetes mellitus

Ocular toxoplasmosis may be remarkably atypical in situations of evident immunosuppression such as acquired immunodeficiency syndrome, malignancy, and use of chronic immunosuppressive drug therapy.7 Aggressive forms in immunocompetent hosts are very rare.1–3 We present a case of severe, bilateral necrotising retinitis by Toxoplasma gondii initially misdiagnosed as an acute retinal necrosis (ARN) syndrome, in a patient with systemic lupus erythematosus (SLE) and diabetes mellitus type 2, who was taking medium dose prednisone.

Case report

A 47 year old woman reported a 3 month history of rapid visual loss in the right eye followed by a decrease in her left eye vision 2 months later. Twenty days before the onset of ocular symptoms the patient had a seizure. Her medical history showed a SLE,1 type 1 diabetes mellitus, and use of chronic immunosuppressives such as acquired immunodeficiency syndrome, malignancy, and use of chronic immunosuppressive drug therapy.7 Aggressive forms in immunocompetent hosts are very rare.1–3 We present a case of severe, bilateral necrotising retinitis by Toxoplasma gondii initially misdiagnosed as an acute retinal necrosis (ARN) syndrome, in a patient with systemic lupus erythematosus (SLE) and diabetes mellitus type 2, who was taking medium dose prednisone.

A 47 year old woman reported a 3 month history of rapid visual loss in the right eye followed by a decrease in her left eye vision 2 months later. Twenty days before the onset of ocular symptoms the patient had a seizure. Her medical history showed a SLE, type 1 diabetes mellitus, and use of chronic immunosuppressive drug therapy. Aggressive forms in immunocompetent hosts are very rare. We present a case of severe, bilateral necrotising retinitis by Toxoplasma gondii initially misdiagnosed as an acute retinal necrosis (ARN) syndrome, in a patient with systemic lupus erythematosus (SLE) and diabetes mellitus type 2, who was taking medium dose prednisone.

Cerebral spinal fluid analysis showed pleocytosis, hypergammaglobulinaemia, and negative serology, including VDRL. Complement level was normal, anti-double stranded DNA and anti-cardiolipin (ACL) antibodies were negative, and activated partial thromboplastin time (aPTT) was normal, not fulfilling the international consensus criteria to anti-phospholipid syndrome. Serum anti-Toxoplasma and anti-herpes virus IgG were positive by enzyme immunoassays, while anti-HIV-1 and HIV-2 was negative. Tests for specific IgM were all negative; serum FTA-Abs was positive; VDRL was negative. Complete blood count and platelets were normal. Chest x-ray was also normal.

A presumptive diagnosis of ARN was made in a patient with active systemic lupus disease. Intravenous aciclovir was introduced and prednisone therapy was maintained.

Owing to failure of the antiviral treatment and ocular disease progression, the patient underwent a chorioretinal biopsy of the right eye for a definite diagnosis, mainly to discharge a tumoral retinachoroidal infiltration. Two blocks of choroid and retina, and also a vitreous sample, were obtained. Polymerase chain reaction (PCR) was unexpectedly positive for T gondii and negative for the herpesvirus family (CMV, HSV-1 and HIV-2, VZV), Treponema pallidum, and Mycobacterium tuberculosis. The biopsy showed a necrotic retina, with few remaining retinal cells. Within the necrotic retina there were occasional lymphocytes and a number of T gondii cysts (Fig 1C). The choroid was densely infiltrated with lymphocytes and plasma cells (Fig 1D). T gondii in the necrotic retina was confirmed by immunohistochemistry (Fig 1E). Intraocular cyst walls, viable T toplasoma gondii bradyzoites bearing micronemes, polysaccharide granules, and apical complex were observed at electron microscopy (Fig 1F). Desmont’s coefficient was negative (anti-T gondii vitreous titre = 2256; anti-T gondii serous titre = 2736; total vitreous IgG = 678 mg/dl; total serous IgG = 1314 mg/dl).

Figure 1 (A) Fundus appearance of the left eye. (B) Fundus appearance of the right eye. (C) Light micrograph shows necrotic retina with occasional inflammatory cells and Toxoplasma cyst (arrow). (D) Light micrograph shows the necrotic retinal pigment epithelium with Toxoplasma cysts (arrow) and the choroid with a dense infiltrate of lymphocyte and plasma cells (haematoxylin and eosin, bar = 10 μm). (E) Immunohistochemistry with alkaline phosphatase. Two Toxoplasma cysts (arrow) positively dyed pink (bar = 10 μm). (F) Electron micrograph of a paraffin embedded tissue post processed for electron microscopy of the chorioretinal biopsy shows two Toxoplasma cysts with micronemes (inset, arrow) and white spheres with hazy borders amylopectin granules (inset, asterisk). The inset shows higher magnification of a bradyzoite, showing apical complex structure. Magnification is represented in standard bars.

www.bjophthalmol.com
Based on these results, aciclovir was discontinued and oral anti-Toxoplasma treatment was initiated with pyrimethamine, sulfadiazine, and folic acid supplementation. After a 1 month treatment retinal lesions started to heal, yet no improvement of visual acuity was observed.

Comment

The present case was atypical because of an extensive bilateral necrotising retinitis and obliterative vasculitis, with no pre-existing chorioretinal scars. Three factors could have conferred a mild degree of immunosuppression to this patient: SLE, diabetes mellitus, and prednisone at medium dose. It is recognised that retinal vasculitis and immunosuppression increase the risk of a herpetic and, to a lesser extent, a toxoplasmic, infection. Ocular toxoplasmosis associated with collagen vascular disorders is a rare event and has been described after aggressive immunosuppressive therapy. On the other hand, retinal vasculitis occurs in less than 10% of SLE patients, particularly in those presenting with antiphospholipid syndrome, which makes them susceptible to retinal inflammatory processes. In the present case, laboratory findings consistent with antiphospholipid syndrome were absent. The pre-existence of widespread SLE retinal vasculopathy could be inferred by the active lupus central nervous system disease. Therefore we speculate that the active SLE associated with diabetes mellitus and the use of corticosteroids increased the patient’s susceptibility to infection leading to this atypically severe toxoplasmic retinitis.

The causative agent was initially diagnosed as T. gondii based on PCR analysis of a vitreous discharge any tumoral infiltration. Based on these results, aciclovir was discontinued and oral anti-Toxoplasma treatment was initiated with pyrimethamine, sulfadiazine, and folic acid supplementation. After a 1 month treatment retinal lesions started to heal, yet no improvement of visual acuity was observed.

Traumatic high flow fistulas may present with proptosis, eyelid oedema, and conjunctival chemosis, and are often easily identified clinically. Spontaneous, frequently low flow fistulas may present with progressive unilateral or bilateral injection, and may be more difficult to diagnose.

There is, however, an infrequent syndrome of ocular injection and increased IOP which is idiopathic. Although originally described by Minas and Podos,6 the same entity is termed the Radius-Maumenee syndrome7 in the German literature.7,8 In one report 10 of 64 patients with glaucoma due to elevated episcleral venous pressure had this syndrome.7 In another report of six patients with unilateral dilated episcleral veins and one patient with bilateral involvement, the IOP in the affected eyes ranged between 21 and 44 mm Hg.10 In all six patients with apparently unilateral involvement the IOP was higher in the eye with the dilated vessels. Episcleral venous pressure was measured to be twice the normal value in the affected eyes of these patients.

Catheter arteriography in these patients is normal, without abnormal arteriovenous communications.9 Other adjunctive testing, including neuroimaging, orbital venography, and fluorescein angiography are also normal.9 Although abnormalities in ocular blood flow have been suggested, the pathogenesis of this condition remains unclear.

Orbital colour Doppler imaging provides a non-invasive means of imaging orbital and ocular blood flow and, in patients with fistulas, characteristically shows reversal of blood flow in a dilated superior ophthalmic vein.9 The superior ophthalmic veins were of normal calibre in our patient, and both orbits showed normal retrograde flow in the orbital veins. Similar findings were reported in the only other patient with this syndrome who underwent orbital colour Doppler imaging, and increased arterial and venous flow in the episcleral vessels was noted in the eye with dilated episcleral vessels; however, the images of the ultrasonography were not published.11 We did not measure the episcleral blood flow in our patient.

Although the cause of this disorder remains elusive it should be distinguished from other disorders, most commonly the arteriovenous fistula (Table 1), which can result in dilated episcleral vessels and increased IOP in patients with IDEV a congenital abnormality in...
vascularity and familial predisposition have been suggested as the cause; however, some reports suggest that the ocular injection is acquired.

Treatments have focused on reducing IOP with aqueous suppression. Filtration surgery has been favoured by some, and in one patient who underwent trabeculectomy the IOP was reduced but the dilated episcleral veins remained unchanged. Presumably an alteration in aqueous outflow would preclude the use of IOP lowering agents which increase uveoscleral outflow; however, the earlier reports of IDEV preceded the availability of these agents.

All hypotheses of the mechanisms of IDEV, however, involve increased episcleral blood flow. In the case of the dilated episcleral veins, increased pressure of dilated episcleral veins with aqueous suppression may play a role in the development of peripheral anterior synechiae. This would explain the low IOP readings after filtration surgery. In one patient with aqueous suppression, filtration surgery has been suggested as the cause of peripheral anterior synechiae.

In another patient, the increased episcleral blood flow with aqueous suppression may be due to an increase in vascular permeability or increased blood viscosity. This may lead to increased episcleral blood flow and thereby explain the development of peripheral anterior synechiae.

Several cases of peripheral anterior synechiae with increased episcleral blood flow have been reported. In one case, peripheral anterior synechiae developed after laser trabeculoplasty with aqueous suppression. In another case, peripheral anterior synechiae developed after laser trabeculoplasty without aqueous suppression. In a third case, peripheral anterior synechiae developed after laser trabeculoplasty with aqueous suppression. In a fourth case, peripheral anterior synechiae developed after laser trabeculoplasty without aqueous suppression.

It is likely that increased episcleral blood flow with aqueous suppression may play a role in the development of peripheral anterior synechiae. However, further research is needed to confirm this hypothesis.

Trypan blue assisted descemetoctomy for inadvertently retained Descemet’s membranes after penetrating keratoplasty
The presence of a retrocorneal membrane following penetrating keratoplasty is a known entity. While the inflammatory membranes usually disappear with the use of topical steroids or topical immunosuppressive agents, there are cases where the inflammatory membranes persist.

Case 1
A 27 year old man underwent penetrating keratoplasty in his left eye for congenital hereditary endothelial dystrophy (CHED). The host cornea was initially trephined to 90% of the corneal depth with a 7.5 mm trephine (Storz Ophthalmics, St Louis, MO, USA). The anterior chamber was entered with a blade and the host cut was completed with corneal scissors. An 8 mm donor button was anchored with 16 interrupted sutures (10-0 monofilament nylon). On the first postoperative day, slit lamp biomicroscopy revealed a retained Descemet’s membrane and a supernumerary anterior chamber. The graft was clear with a best corrected visual acuity (BCVA) of 20/40.

At 1 week, an additional inflammatory membrane developed in the anterior chamber. The graft was clear with an increased intraocular pressure of 21 mm Hg. At 2 weeks, the BCVA was 20/40 and there was no active inflammation in the anterior chamber.

Case 2
A 26 year old man underwent penetrating keratoplasty in his right eye for CHED with the same surgical technique and graft size as in Case 1. On the first postoperative day, a transparent retained Descemet’s membrane was noticed on slit lamp biomicroscopy. The graft was clear with no active inflammation in the anterior chamber and BCVA was 20/40.

Based on our experience of Case 1 regarding the development of inflammatory membrane, we decided to excise the retained Descemet’s membrane at 1 week using the same technique. Postoperatively, the patients received 2 hourly 0.1% betamethasone sodium phosphate eye drops, 0.3% ciprofloxacin eye drops four times daily and preservative-free artificial tears eye drops four times daily. At 2 months of follow up, the grafts were clear with a single anterior chamber and the visual acuity of 20/40 was maintained in both the eyes.

Comment
Both these cases with retained host Descemet’s membrane following penetrating keratoplasty were that of CHED. In these cases, longstanding stromal oedema may cause loosening of the attachment of the Descemet’s membrane and predispose its separation from the overlying stroma as has also been reported in a case of interstitial keratitis. Hence, inadvertent, incomplete trephination of such oedematous corneas may cause retention of the host Descemet’s membrane. Although both the patients had good vision and the grafts and retrocorneal membranes were clear, we decided to excise these membranes as an inflammatory membrane started growing in the first case. We thought that the host’s retained Descemet’s membrane is acting as a scaffold and further growth of inflammatory membranes may jeopardise the graft.

Trypan blue is commonly used to stain the anterior lens capsule for capsulorhexis in cataract surgery. As both lens capsule and
Descemet's membrane are basement membranes, we attempted to stain the retained Descemet's layer with trypan blue to enhance its visibility during the surgery. In both the cases an optimal staining of the membranes helped in achieving a controlled circular tearing of the membrane without affecting graft clarity.

We called our technique of dye assisted removal of retained Descemet's membrane “descemetorhexis” as the retained Descemet's membrane were torn in a circular fashion at the graft-host junction.

**Orbital haemorrhage complication following postoperative thrombolysis**

Thrombolytic agents, such as tissue plasminogen activator (tPA), are commonly employed early in the management of patients with acute myocardial infarction. In this setting the rapid thrombolysis of coronary thrombi achieves reperfusion and has well established survival benefits. Often the anticoagulant heparin is simultaneously administered to prevent reocclusion. Both therapies may have haemorrhagic complications. We report a case of retrobulbar haemorrhage as a complication of thrombolytic therapy instituted for an acute myocardial infarction occurring 2 days after routine cataract surgery.

**Case report**

A 72 year old man underwent uncomplicated right phacoemulsification and posterior chamber intraocular lens implantation. Before surgery, a peribulbar block was administered, using a single transcutaneous inferior lateral injection of local anaesthetic. The patient had a background of hypertension and hypercholesterolaemia. His medications included amlopidine besylate, simvastatin, and aspirin. The aspirin had been stopped 1 week before surgery. The patient had not had any past medical history of a haematological disorder.

Two months previously he had undergone uneventful left sided cataract surgery. The day 1 postoperative ocular examination was unremarkable and the patient was generally well. Two days following surgery the patient was admitted to the emergency department with an acute inferolateral myocardial infarct. The attending cardiologist and the patient's ophthalmologist agreed that the benefits of thrombolysis outweighed the risk to the eye and vision. A 10 unit dose of tPA was administered to the patient with a concomitant heparin infusion; this was followed half an hour later by a second dose. Aspirin was also prescribed.

Two hours after the initial dose of tPA peri-orbital swelling of the right eye was noted. Over the next hour there was increasing perilobital oedema and the patient reported mild ocular discomfort, loss of vision, nausea, and vomiting. During one episode of emesis there was an abrupt onset of frank pericocular haemorrhage. The heparin infusion was stopped. Examination of the affected eye revealed proptosis, subconjunctival haemorrhage, a retinal venous papillary defect, a hazy cornea, and severely restricted extraocular movements. Vision was no perception of light. A computed tomograph scan demonstrated a large retrobulbar haematoma in proximity of the lateral rectus muscle (Fig 1).

The patient was given intravenous acetazolamide and hydrocortisone. Cytomotomy and cannulization resulted in a slight improvement in adduction of the left eye, however vision remained at no perception of light.

With the heparin ceased the patient was at increased risk of recurrent thrombosis and that evening was transferred to a centre with the facility for orbitotomy where he was treated for his coronary artery disease. The probability that eyesight would return thereafter was considered remote and the retrobulbar haemorrhage was managed conservatively. The patient underwent corneal angioplasty with placement of a stent and placed on clopidogrel and aspirin.

Bleeding of the right orbit continued for a further 48 hours; thereafter extraocular movements gradually improved, perilobital oedema subsided, and the degree of proptosis reduced. On discharge, 8 days after admission, vision remained at no perception of light.

**Comment**

Haemorrhage represents the most common and important complication of thrombolytic therapy. Relative contraindications to the use of thrombolytic agents include major surgery in the previous 3 weeks and non-compressible vascular punctures.

There are several reports of postoperative haemorrhagic ocular complications following the use of systemic thrombolytic agents including a total hyphaema following streptokinase administration 8 days after extracapsular cataract extraction, sub-Tenon's haemorrhage following streptokinase given 2 hours after scleral buckling surgery, and three cases of orbital haemorrhage following thrombolytic therapy administered with 1-5 days after cataract or eyelid surgery.

The retrobulbar haemorrhage in our patient is most likely the result of thrombolytic therapy and the result of lyse of a haemostatic plug in an arterial vessel within the orbit that was punctured during the delivery of the anaesthetic. Reformation of a haemostatic plug was probably inhibited by the antiplatelet and anticoagulant effects of aspirin and heparin.

Prompt recognition and immediate delivery of appropriate treatment are important in the preservation of good visual acuity. In our case lateral cantholysis did not adequately relieve the retro-orbital haemorrhage. The extent of our patient's coronary artery disease precluded the general anaesthetic necessary for orbitotomy and, because of its life threatening nature, its management took precedence.

Pertinent in the consideration of decompressive orbitotomy was the possibility of ongoing systemic effects of tPA, heparin, and aspirin. The circulating half life of tPA is 6 minutes, although the duration of the local lytic effect from fibrin bound tPA is not known. The effective half life of heparin is approximately 1 hour. Many hours after their last administration, neither was likely to be having any ongoing systemic effects of concern. The duration of action of aspirin, however, continues into the life of affected platelets, 7-10 days, as it irreversibly inhibits the enzyme responsible for platelet aggregation. This effect gradually dissipates as new platelets are formed. Although of necessarily prohibitive to surgery, the implications of ongoing platelet dysfunction include difficulty in achieving haemostasis with the potential for poor surgical visualisation and excessive blood loss.

Primary percutaneous transluminal coronary angioplasty (PTCA) may be performed as an alternative to thrombolytic therapy. With improved mortality and lower rates of intra-cranial haemorrhage, primary PTCA would seem an attractive alternative especially in those patients at high risk of haemorrhage. However, it should be noted that a case of orbital haemorrhage following PTCA has also been reported.

This patient originally had bilateral cataracts and 2 months earlier had undergone uneventful left sided cataract surgery. Had the cataract operations been conducted in close succession, a similar situation as described here may have presented the potential for complete blindness. Although rare, such unforeseen circumstances may need to be considered when determining order of successive surgery for bilateral cataracts.

This case highlights that, in the context of relative contraindications to thrombolytic therapy, cataract surgery with injected local anaesthesia is to be considered major surgery. Thrombolytic therapy required shortly after cataract surgery has the potential to result in sight threatening haemorrhagic complications.

The IOL flip: rescue for foldable lens implantation gone wrong

Phacoemulsification surgery offers many advantages in comparison with extracapsular cataract extraction (ECCE). In particular, faster visual rehabilitation and better control over surgically induced astigmatism are well established benefits over ECCE.1,2 These advantages are largely due to the small size of the cataract incision.3

Inadvertent insertion of a posterior chamber intraocular lens (IOL) with a reversed front to back orientation is a surgical dilemma that will present occasionally. Ancodatal evidence suggests that while this problem is not common, it is not a rare event. Reported data place the frequency between 1.0–1.3%.4

Often, IOL inversion is only recognised after completion of one smooth action. It is important to have the capsular bag is lost or in doubt, as there is a potential for worsen- ing any capsular rent. The idea of the technique is to cause a rota- tional movement about the diameter of the IOL optic, similar to flipping a coin, while at the same time protecting the corneal en- dothelium and posterior capsule. The technique proceeds as follows:

1. The anterior chamber is deepened with viscoelastic to create space between the optic/haptics and the endothelium. The capsule bag behind the optic is distended with visco- elastic to facilitate safe flipping of the IOL.

2. The rotational force on the optic is generated by the careful placement of two intraocular instruments. The tip of the haptic is manipulated as a Sinskey hook and mushroom. Their long horizontal segments ensure a controlled rotation of the optic about the central axis. For the right handed surgeon, a Sinskey hook held in the right hand is placed behind the optic, to the right of the optic centre (Fig 1A). To initiate the flip, the mushroom is then raised towards the cornea while simultane- ously the Sinskey hook is pushed posteriorly. These movements take place about an axis passing through the diameter of the optic (Fig 1B), forcing the IOL to flip. The haptics then do a 180 degree slow, controlled sweep into the correct position, lagging slightly behind the optic. The manipulation should be comp- leted in one smooth action. It is important to ensure that flipping occurs in the anticklock- wise direction so that the leading haptic’s free end does not point towards and threaten the posterior capsule. There is usually adequate room between the corneal endothelium and posterior capsule in most eyes to accommo- date the vertical position of the optic during the flip. Although it is possible to perform this manoeuvre with the lens held by the Kelman-McPherson forceps, slight misalignment of the jaws, which often is present, could result in sudden and uncontrolled twisting and an uncontrolled flip so this is not recommended.

**Comment**

Most of the problems causing IOL inversion are related to inadequate attention to details during lens insertion. The use of injectable IOL systems, particularly those that require elaborate rotational movements on the part of the surgeon in order to correctly place the IOL within the capsular bag may result in an inverted IOL. Correct insertion of the IOL within the cartridge is a guarantee of correct placement into the eye. In the AMO Unfolder system, particular care has to be taken to avoid inver- sion. During injection, the free end of the leading haptic has to be directed to the surgeon’s left, with the loop held in the hori- zontal position at all times via a series of pro- motion movements of the right handed sur- geon’s wrist, in order for the IOL to be correctly oriented. Failure to pronate the wrist in an adequate and timely fashion will result in an incorrect placement. Other systems that do not require complicated manipulations may reduce the possibility of incorrect im- plantation.

Forceps insertion of foldable IOLs also may lead to reversed placement. The correct orien- tation of the IOL should be checked before folding in all cases, particularly if the lens has been dropped during transfer. Incorrect orient- ation is indicated by an “S” configuration formed by the lens haptics and optic. Recogni- tion of the “S” must signal to the surgeon to “stop” and check. Occasionally the trailing haptic may be trapped within the incision by the jaws of the inserting forceps, inducing spontaneous flipping within the eye. Recognised early, this can be aborted by placing the forceps tips over the optic to prevent further rotation, while releasing the trapped haptic with Kelman-McPherson forceps.

Although inverted lens implantation is eminently preventable with proper attention at each step of lens implantation, it still is a problem that occurs with enough frequency to be of concern. Should the surgeon decide that correction of the reversal is appropriate, the IOL flip offers a simple, quick and safe way out of a tight spot.

Recovery of visual function in a patient with birdshot chorioretinitis

Birdshot chorioretinopathy (BSCR) is a rare inflammatory disease, which generally follows a chronic course of progressive loss of vision to 6/60 or worse. However, the vision may stabilise or, rarely, improve slightly. Commonly prescribed treatment regimens, including oral steroids, and one or two immunosuppressive agents, may stabilise but generally do not cure the condition.

We describe a case of BSCR in which there was a marked improvement in Snellen acuity and retinal function, measured with wide field multifocal electroretinography (WF-mfERG) in a patient intolerant of conventional treatment, who self medicated with an antioxidant preparation.

Case report
A 53 year old white woman was referred with a 2 year history of decreased vision and floaters affecting both eyes. Snellen acuity was 6/24, N8 in the right eye and 6/12, N8 in the left eye. Moderate vitritis, cystoid macular oedema, swelling of the optic discs, and the presence of scattered, deep, pale creamy white lesions, were compatible with a diagnosis of BSCR, supported by positive HLA-A29 serology.

A reducing dose of oral prednisolone in conjunction with cyclosporin was commenced. There was no improvement in visual symptoms and, owing to the development of cellulitis around the umbilicus, cyclosporin was stopped.

She was referred to the regional uveitis service. WF-mfERG was performed at presentation, using a custom built system comprising a 61 hexagonal array. This test facilitates localised assessment of retinal function, within a 90° retinal field. WF-mfERG showed a global reduction of P1 amplitude responses in both eyes (Fig 1B). A lower dose of cyclosporin was tried but subsequently discontinued because of significant gastrointestinal symptoms.

Over the next 18 months, tacrolimus, mycophenolate, and mycophenolate were all prescribed separately in conjunction with a maintenance dose of 5 mg of prednisolone. Tacrolimus 1 mg twice daily was discontinued after 2 weeks because of intolerable side effects. Treatment with azathioprine 50 mg three times daily continued for 7 months with no improvement in vision. Mycophenolate 1 mg twice daily was stopped at the patient’s request after a year, owing to progressive deterioration of vision and a general feeling of malaise. In addition, prednisolone was tailed down to a maintenance dose of 5 mg of prednisolone.

A video clip of the technique is available on the BJO website www.bjophthalmol.com/supplemental

off and stopped after 20 months of steroid treatment. The visual acuity at this stage was 6/36, N4 and 6/12, N14, and the patient was taking no conventional medication. The amplitude of the central and peripheral WF-mfERG responses recorded a year after presentation had deteriorated further (Fig 1C).

Three months after discontinuing all conventional treatment, the patient began to self medicate with an antioxidant preparation, the contents of which included white and maritime pine bark, grape seed extract, β-carotene, and vitamins C and E (Table 1). After 6 months, Snellen acuity had improved to 6/15, N10 in the right eye and 6/9, N8 in the left. In addition, the amplitude of the central WF-mfERG responses had improved from 21 nV to 91.5 nV in the right eye and from 35 nV to 167 nV in the left eye (normal range 74–122 nV). The amplitude and implicit time of the average peripheral WF-mfERG responses had also improved in both eyes (Fig 1D).

She continued on the antioxidant regimen and 6 months later, the visual acuity and retinal function in both eyes, recorded with the WF-mfERG, had remained stable.

Comment

WF-mfERG investigations showed a marked improvement in visual function of both eyes after commencing the antioxidant preparation. This observation mirrored the recovery of Snellen acuity but did not correlate with Goldmann perimetry findings (Fig 1E and F).

Antioxidants are thought to scavenge free radicals produced in the retina following light absorption, and thus prevent cellular damage that they may produce. The pathophysiology of BSCR is unclear; therefore the role of antioxidants in reversing the damage caused by BSCR is purely speculative. In this case it is unclear whether the improvement in visual function, recorded with WF-mfERG was spontaneous, whether it was a late result of previous conventional treatment, or whether it was secondary to the commencement of a complex non-prescribed antioxidant preparation. The role of antioxidant treatment in BSCR needs further appraisal, perhaps using the HLA-A29 transgenic mouse, which has been shown to spontaneously develop a retinopathy that is histologically very similar to that found in BSCR.6

Central retinal venous occlusion with co-existent thrombotic thrombocytopenic purpura and anti-phospholipid syndrome

Central retinal venous occlusion usually occurs in elderly patients with known risk factors such as raised intraocular pressure, arterial hypertension, atherosclerotic disease, or diabetes mellitus. In addition, central retinal venous occlusion infrequently occurs in individuals with hyperviscosity from leukaemia, polycythaemia, Waldenstrom’s macroglobulinaemia, sickle cell disease, and periphereitis. However, it has also been described in patients with antiphospholipid antibodies7 and rarely in patients with thrombotic thrombocytopenic purpura (TTP) (pentad of fever, microangiopathic haemolytic anaemia, thrombocytopenia, neurological abnormalities, and renal impairment). We describe central retinal venous occlusion in a 26 year old female patient with systemic lupus erythematosus (SLE), in whom both TTP and antiphospholipid syndrome (APS) appear to have contributed to the pathogenesis. To our knowledge, co-existence of TTP and APS has not been previously reported in a case of central retinal venous occlusion.

Case report

The patient presented in 1994, aged 19, with arthralgia and fatigue. Haemoglobin was 3.5 g/dl and platelet count 15 × 10⁹. Investigations revealed SLE (antinuclear antibodies were positive at a titre of 1:640 and anti-double stranded DNA antibodies were 1:320)
with Evans’ syndrome (combined auto-immune haemolytic anaemia and immune thrombocytopenia). Tests for APS were not performed. The patient responded to corticosteroids and azathioprine, which were reduced and finally stopped in April 1997. She remained well until hospitalised in February 2001 with fever of 38°C, gross haematuria, malaise, poor concentration, and headache. Haemoglobin was 7.5 g/dl (Direct Coombs’ test negative) and platelet count was 1 × 10^11/L. Serum creatinine was 244 mmol/l and activated partial thromboplastin time was prolonged at 93 seconds. IgG anticardiolipin antibodies were elevated (18 GPL units/ml) and anti-β2-glycoprotein I was detected by a positive kaolin clotting time index and a dilute Russell viper venom test. C3 and C4 complement components were reduced and finally stopped in April 1997.

In a recent review, anticardiolipin antibodies has been reported in some cases of TTP in association with SLE, possibly by causing endothelial damage in the microvasculature. TTP is a rare but recognised association with central retinal vein occlusion while a high prevalence of anticardiolipin antibodies has been reported in patients with vaso-occlusive retinopathy except from conventional risk factors. However, to our knowledge, this present case of central retinal venous occlusion is unique because of co-existent APS and TTP secondary to SLE. Although aggressive immunosuppressive therapy, aspirin and cryoprecipitate poor FFP led to control of APS and TTP, the severe visual impairment due to central retinal venous occlusion failed to recover.

Further considerations of retinopathy with renal failure

We were interested to read the letter by Patel et al. reporting the unusual and striking fundus appearance of retinal arteriolar calcification in association with chronic renal failure. However, we feel that two important conditions have been omitted from the comment, which merit further discussion. Firstly, Monckeberg’s sclerosis, which in its classic form is characterised by ‘pipe stem’ calcific deposition in the medial coat of muscular arteries in middle aged and elderly individuals, and is described with widespread systemic distribution. Interestingly though, a juvenile form is seen, particularly in association with chronic renal failure and diabetes. The pathological mechanism of Monckeberg’s sclerosis is uncertain, but is thought to encompass elements both of dystrophic and metastatic calcification. In the reported case, it would be of interest to know if there was any evidence of vascular calcification elsewhere in this individual, or whether it was localised to the retinal arterioles only.

Secondly, Senior-Loken syndrome (renal-retinal syndrome, nephropathies associated with retinitis pigmentosa, or retinal aplasia) is also germane to this discussion. Nephropathies is a major cause of progressive medullary cystic renal disease leading to chronic renal failure in adolescents. It is associated with a variable retinal phenotype, a reflection of both clinical and genetic heterogeneity. When associated with retinitis pigmentosa, there is an absence of the classic bone spicule pigmentation, but optic nerve head pallor and attenuation of the blood vessels is seen. Also, electroretinographic alterations have been reported in nephropathies despite normal a normal fundus examination. In view of the phenotypic overlap seen with the reported case, results of electroretinography would be pertinent to the discussion. We would also add that a vascular analysis at the known loci associated with Senior-Loken syndrome, which could potentially reveal an interesting new allelic variant.

Finally, while the fundus photograph elegantly demonstrates the stark changes seen in the retinal vasculature; this evidence could be further augmented by the addition of an ultrasound B-scan image demonstrating the pathognomonic echogenic features of intraretinal calcification.

Comments on myopia in secondary school students in Tanzania

I refer to the interesting article by Wedner et al published recently in the BJO. The authors have concluded, without enough justification, that “an eye screening programme for significant refractive errors is indicated in this population.” I believe more data are required for such a conclusion.

Wedner et al could have reported the true positive predictive rate for the detection of myopia using the stated referral criterion of “worse than 6/12” on the Snellen visual acuity chart: 141/174 or 81% (95%CI: 74 to 86). However, they have referred to the prevalence of “significant” myopia being 141/2511 or 5.6%.

In epidemiological convention it is incorrect to apply this denominator and report this prevalence rate because the reference standard for the determination of refractive errors—that is, refraction, has not been performed in the majority (2337) of the 2511 students. The positive predictive value of a screening test is influenced by the prevalence of the condition to be screened (that is, myopia). Nevertheless, without experimental data on the false negative errors could escape the best compromise threshold on visual acuity testing. If a subject could pass the visual acuity criterion on one occasion, one should not assume that he is not myopic. Hence there have such low myopia that he is functionally normal.

Left handed non-dominant hand phacoemulsification

We appreciate the commendable work by Kageyama et al, which was published in the BJO. We have also studied the results of left handed non-dominant hand phacoemulsification prospectively, performed in left eyes of 29 patients with an immature senile cataract and against the rule astigmatism. Phacoemulsification was performed by an experienced surgeon (RBV) under peribulbar anaesthesia. The surgeon sat at the head end of the patient while performing phacoemulsification (on left eyes). In all the cases, a 3.2 mm clear corneal temporal incision was made with a diamond knife held in the left hand of the surgeon. Following a continuous curvilinear capsulorhexis and hydroprocedures a phaco chop nucleus was performed using Storz Pro- tégé phaco machine. The chopper was held in the right hand of the surgeon and inserted from the 12 o’clock side port and the phaco probe was held in the left hand of the surgeon and introduced from the main incision on the temporal side. This was followed by automated irrigation aspiration and implantation of an Acrysof foldable intraocular lens (Alcon MA 60 BA) in the capsular bag.

In our study of 29 patients the mean age of the patients was slightly younger, 63.50 (SD 9.61) years (range 43–80 years), than patients of Kageyama et al. Out of 29 eyes, nuclear hardness was grade 3 or more in 17 eyes in our series. It would be worthwhile to know the nuclear hardness in the series reported by Kageyama et al as the manoeuvres in hard cataract may be more difficult to perform with the non-dominant hand. The mean ultrasound power used in our cases was 25.7% (9.5%) and the mean effective phacoemulsification time was 18 (11) seconds. No posterior capsular tear or vitreous loss was present in our cases and this could be attributed to the fact that an experienced surgeon performed the surgery. However, were there any anterior capsular tears noted by Kageyama et al, which occurred in two eyes in our series during the chopping procedure? Nevertheless, none of these cases had a posterior extension of the tear with vitreous loss. Twenty seven eyes (93.1%) achieved a best corrected visual acuity of 20/20 at 4 weeks after the surgery, while two eyes had a best corrected visual acuity of 20/40 because of the presence of age related macular degeneration. It would be also worthwhile to know the amount of astigmatism preoperatively and postoperatively reported by Kageyama et al, as one of the advantages of a temporal incision phaco is less surgically induced astigmatism. The mean preoperative keratometric ATR astigmatism was 0.54 (0.44) D (range 0.25 to 2 D) and the mean postoperative ATR astigmatism was 0.25 (0.64) D (range 0.75 to 1.75D) (Wilcoxon signed rank test, p = 0.0267) in our series. We had a similar mean endothelial loss of 6.02% at the end of 12 weeks.

Clear corneal non-dominant hand phacoemulsification is indeed a safe and efficacious method. This obviates the need for a surgeon to change position between cases. In addition, the dominant hand is utilised for chopping, which makes the non-dominant hand the most active instrument, while the non-dominant hand holds the ultrasound hand piece as a passive instrument in the centre of the capsular bag. This helps to reduce the use of ultrasound energy for nuclear management, as the chopper is the primary instrument used for mechanical disintegration of the nucleus.

Left handed non-dominant hand phacoemulsification

This interesting paper seems to lack one essential attribute—common sense. To operate “from the top” with the non-dominant hand in the temporal position surely does not equate to a comfortable operating position for the surgeon. A better and more sensible solution, to avoid moving equipment around between cases, is to book only right eyes on one operating list, and left eyes on another.

We have to be careful not to trivialise an operation that is becoming faster and faster to perform as ultrasound and lens technology improves. Perhaps non-dominant handed surgeons could be replaced by dominant-handed technicians. I know which hand I would rather my surgeon use.

Second Sight
Second Sight, a UK based charity whose aims are to eliminate the backlog of cataract blind in India by the year 2020 and to establish strong links between Indian and British ophthalmologists, is regularly sending volunteer surgeons to India. Details can be found at the charity website (www.secondsight.org.uk) or by contacting Dr Lucy Mathen (lucymathen@yahoo.com).

SPecific Eye ConditionS (SPECS)
SPecific Eye ConditionS (SPECS) is a not for profit organisation which acts as an umbrella organisation for support groups of any conditions or syndrome with an integral eye disorder. SPECS represents over fifty different organisations related to eye disorders ranging from conditions that are relatively common to very rare syndromes. We also include groups who offer support of a more general nature to visually impaired and blind people. Support groups meet regularly in the Boardroom at Moorfields Eye Hospital to offer support to each other, share experiences, and explore new ways of working together. The website www.eyeconditions.org.uk acts as a portal giving direct access to support groups’ own sites. The SPECS web page is a valuable resource for professionals and may also be of interest to people with a visual impairment or who are blind. For further details about SPECS contact: Kay Parkinson, SPECS Development Officer (tel: +44 (0)1803 524238; email: k@eyeconditions.org.uk; web site: www.eyeconditions.org.uk).

The British Retinitis Pigmentosa Society
The British Retinitis Pigmentosa Society (BRPS) was formed in 1975 to bring together people with retinitis pigmentosa and their families. The principle aims of BRPS are to raise funds to support the programme of medical research into an eventual cure for this hereditary disease, and through the BRPS welfare service, help members and their families cope with the everyday concerns caused by retinitis pigmentosa. Part of the welfare service is the telephone help line (+44 (0)1280 860 363), which is a useful resource for any queries or worries relating to the problems retinitis pigmentosa can bring. This service is especially valuable for those recently diagnosed with retinitis pigmentosa, and all calls are taken in the strictest confidence. Many people with retinitis pigmentosa have found the Society helpful, providing encouragement and support through the help line, the welfare network, and the BRPS branches throughout the UK. (tel: +44 (0)1280 821 334; email: lynda@brps.demon.co.uk; web site: www.brps.demon.co.uk)

Surgical Eye Expeditions International
Volunteer ophthalmologists in active surgical practice are needed to participate in short term, sight restoring eye surgery clinics around the world.
