Br J Ophthalmol 2004;88:1247–1251. doi: 10.1136/bjo.2003.039784

Aim: To study the MUC5AC and the blood group related antigen expression in ocular cicatricial pemphigoid (OCP) according to the distribution of Lewis and secretor phenotypes in OCP patients compared to normal subjects.

Methods: Immunostaining was performed on conjunctival biopsy specimens from 22 consecutive patients suffering from OCP, using monoclonal antibodies (Mabs) directed against the peptidic core MUC5AC mucin (anti-M1/MUC5AC Mabs) and against the saccharide moieties (anti-blood group related antigens). These latter included anti-Le^a, anti-Le^b, anti-sialyl Le^a, and H type 2 Mabs, which immunoreact with Lewis positive and non-secretor (Le^a), Lewis positive and secretor (Le^b), Lewis positive (sialyl Le^a), and secretor (H type 2) phenotypes respectively. Serological tests were also performed to confirm the phenotype of each patient. The immunohistopathological patterns and the distribution of Lewis and secretor phenotypes were compared with the results of a previous study in normal individuals.

Results: (1) In OCP patients compared to the normal population, anti-M1 immunoreactivity of goblet cells was unchanged, whereas anti-Le^a, anti-Le^b, and anti-sialyl Le^a immunoreactivities of epithelial and/or goblet cells were markedly decreased. (2) 41% of OCP patients had a non-secretor phenotype, which is statistically significantly more than the estimated incidence of the same phenotype in the French population (20%) ($p \approx 0.04$).

Conclusions: Mucins in OCP patients showed a decreased expression of blood group related antigens whereas the MUC5AC peptidic core detected by anti-M1 Mab remained unchanged. These results also seem to indicate that OCP may be associated with a non-secretor phenotype.

Cicatricial pemphigoid (CP) is a rare systemic mucocutaneous bullous autoimmune disease which affects the eye in 70% of cases.^{1–3} Ocular cicatricial pemphigoid (OCP) is characterised by chronic conjunctivitis, progressive subepithelial fibrosis, fornix foreshortening, symblepharon formation, and dry eye syndrome. Immune deposits at the conjunctival epithelial basement membrane zone are the hallmark of OCP.^{4–6}

Mucus is a tear film component which is crucial for the adherence of the aqueous layer to the superficial epithelial cells of the ocular surface. Mucins are made of flexible threads containing subunits.⁷ These latter contain heavily glycosylated regions (T domains) interspersed with less glycosylated or “naked” stretches of proteins.⁸ Carbohydrate moieties are important components of mucus partly responsible for its viscosity. The blood group related epitopes are well known mucin antigens, mainly located in the glycosylated T domains. Le^a and Le^b antigenic determinants result from the epistatic interaction of the products of Lewis (*Le* or

FUT3/5) and Secretor (*Se* or *FUT2*) genes on the Le^c precursor chain.⁸ These genes encode for two different fucosyltransferases which each transfers one fucose molecule onto two distinct sites of the Le^c chain to build Le^a and Le^b epitopes. The transfer of two fucose molecules on the Le^c chain by both fucosyltransferases builds the Le^b antigen. Four different phenotypes—namely, Le^a, Le^b, Le^c and Le^d—are thus generated depending on the enzyme activities of these two fucosyltransferases.⁹ The links between Lewis phenotypes and *Le* and *Se* genes are detailed in table 1.

Mucin M1/MUC5AC peptidic core epitopes, antigens secreted by conjunctival goblet cells, are mainly found in the columnar mucus cells of the gastric surface epithelium.^{10–11} All these epitopes probably are encoded by the same MUC5AC gene.^{12–14}

In dry eye syndrome, mucin distribution and biochemical characteristics, including glycosylation, are modified.¹⁵ However, studies using conventional histological stainings¹⁶ or lectins¹⁷ have failed to show any alteration of carbohydrates in the goblet cells of patients with OCP, which is usually associated with dryness.

The purpose of our study was to immunocharacterise the peptidic antigens of conjunctival mucins and to analyse the distribution of the blood group related antigens with respect to the secretor and Lewis phenotypes in OCP patients.

PATIENTS AND METHODS

Population study

Twenty two patients including 16 biopsy proved OCP patients and six OCP suspects, with a mean age of 65 years (range 26–92 years) were included in the study. The diagnosis of OCP suspect relied on the combination of the following criteria: age over 60, progressive conjunctival fibrosis, association with extraocular involvement, absence of prolonged use of preserved topical medications, absence of systemic and ocular non-autoimmune fibrosing conditions including Stevens-Johnson syndrome, toxic epidermal necrolysis, Sjögren's syndrome, sarcoidosis, lupus, progressive systemic sclerosis, fibrosing infectious conjunctivitis, ocular trauma or burn, rosacea, atopic keratoconjunctivitis, and efficacy of systemic immunosuppressive therapy.

Eighty nine normal individuals who belonged to a previous study were also included.¹⁸ A conjunctival biopsy had been performed during cataract surgery, and the specimens had been processed with the same methods as in this study.

Tissue samples

Conjunctival biopsies were harvested from the bulbar conjunctiva adjacent to the superior limbus after informed consent had been obtained. They were bisected or trisected,

Abbreviations: OCP, ocular cicatricial pemphigoid; Mabs, monoclonal antibodies

Table 1 Lewis phenotypes

Name of phenotype	Le ^a	Le ^b	Le ^c	Le ^d
Structures	βGal 1 3 αFuc1-4βGlcNAc	αFuc1-2βGal 1 3 αFuc1-4βGlcNAc	βGal 1 3 βGlcNAc	αFuc1-2βGal 1 3 βGlcNAc
Secretor(FUT2)	–	+	–	+
Lewis (FUT3/5)	+	+	–	–
Red cell phenotype	Le(a+b–)	Le(a–b+)	Le(a–b–)	Le(a–b–)
Frequency in white people (%)	20	70	1	9
MAbs reactivity				
Anti-Le ^a	+++	–	–	–
Anti-Le ^b	+	+++	–	–
Anti-S Le ^a	+++	+++	–	–
Anti-H-Type 2	–	+++	–	+++

*Anti-Le^b MAb faintly react with Le^a antigen.⁹
Lewis positive (Le (a+b–) and Le (a–b+)) patients can be detected by anti-Le^a, anti-Le^b, and/or anti-sialyl Le^a MAb. Non-secretor patients include those with Le^a phenotype (detected by anti-Le^a MAb) and Le^c phenotype which fails to immunoreact with any anti-Lewis and anti-H type 2 MAb. Secretor patients are detected by anti-Le^b but also by anti-H type 2 MAb.

with one or two pieces processed for direct immunofluorescence and/or direct immunoelectron microscopy, and another piece for immunocharacterisation of mucin epitopes.

This latter piece was fixed in 95% ethanol overnight, as previously described,¹⁶ embedded in paraffin, and then thin serial sections were cut.

Monoclonal antibodies

All MAb except for one (MAb NS-19-9) were provided by our laboratory. They included anti-M1 MAb,^{11–14} and the MAb against the saccharide moieties of mucins. These latter included anti-Le^a (7LE),^{19–21} anti-Le^b (2-25LE),^{9, 22} anti-H type 2 (19-0LE),^{19–21} and anti-sialyl Le^a (NS 19-9)²³ MAb. Anti-Le^b MAb are known to faintly cross react with the Le^a antigen (tables 1 and 2).⁹

The links between the blood group antigen related structures, secretor and Lewis phenotypes and Le and Se genes are detailed in table 1. Lewis positive patients can be detected by anti-Le^a, anti-Le^b, and anti-sialyl Le^a MAb. Non-secretor patients include those with Le^a phenotype (detected by anti-Le^a MAb) and Le^c phenotype which fails to immunoreact with any anti-Lewis MAb. Since the fucosyl-transferase encoded by Se gene also transfers fucose onto a precursor chain different from Le^c chain to build the H type 2 antigen,¹⁰ secretor patients not only are detected by anti-Le^b, but also by anti-H type 2 MAb (table 1).

Immunoperoxidase assay

The sections were deparaffinised and incubated for 30 minutes with the MAb (undiluted hybridoma supernatants).

After three washes in PBS-Tween, the sections were incubated for 30 minutes with sheep anti-mouse Ig antibodies (1/200) bound to peroxidase. After three washes in PBS-Tween, the sections were incubated for 4 minutes with amino-ethylcarbazole containing H₂O₂. Cell nuclei were then stained with 1% haematein. To control the specificity of the immunoreactivity, MAb were absorbed with gastric M1 mucin preparation (100 µg/ml). Semiquantitative grading of the intensity of immunostaining from 0 to 3+ was performed in a masked fashion using light microscopy. Gastroduodenal mucosae of individuals expressing each Lewis and secretor phenotype were used as positive controls as previously described.¹⁰

Serological determination of Lewis phenotypes

Serological Lewis phenotypic determination, obtained using haemagglutination after informed consent of the patients had been obtained, was compared to the phenotypes determined by immunohistochemistry of the conjunctiva.

Statistics

Phenotypic distribution was studied using the Fisher's exact test. Results were considered as statistically significant when the p value was less than 0.05.

RESULTS

**Mucin M1/MUC5AC peptidic core epitopes
Goblet cells**

The number of conjunctival goblet cells was dramatically reduced in OCP patients compared to normal controls. In

Table 2 Immunohistological staining using anti-blood group related antigen MAb on the conjunctiva of the 22 OCP patients and the 89 normal individuals¹⁸

OCP, ocular cicatricial pemphigoid; N, normal conjunctiva; Ph, phenotype; Le^a, anti-Le^a (7LE); S-Le^a, anti-sialyl-Le^a (NS 19-9); Le^b, anti-Le^b (2–25 LE); positive reaction from + to +++ represent increasing number of stained cells and intensity staining; NA, not applicable; –, negative staining; *number of individuals; †goblet cells were found only in 5/7 Le^a OCP patients; ‡goblet cells were found only in 11/13 Le^b OCP patients.

Figure 1 Immunoperoxidase staining of the conjunctiva of a patient with OCP using anti-M1 MAb and haematein counterstaining. The number of goblet cells is markedly decreased, but all goblet cells (arrows) and no epithelial cells were stained with the Mab (magnification $\times 500$)

OCP patients, goblet cells were present in 16 of 22 conjunctival specimens, and less than six goblet cells were counted in the sections of 12 of them (fig 1). However, their cytoplasm expressed the same intense staining with anti-M1 mucin Mabs as the goblet cells of normal conjunctiva without any link between the presence of M1 antigen and Lewis or Secretor phenotypes.

Epithelial cells

Epithelial cells from OCP and normal conjunctivas were not stained with anti-M1 mucin Mabs.

Lewis related epitopes (table 2)

In OCP patients, Lewis related epitopes were exclusively expressed in the conjunctiva of Lewis positive individuals. Le^a , Le^b , and Le^c phenotypes were found in 13, seven, and two patients, respectively. Sialyl Le^a epitopes were expressed in goblet cells and epithelial cells of both Le^a and Le^b individuals as previously described in normal conjunctiva.¹⁸

Goblet cells

Of the 16 OCP conjunctival samples containing goblet cells, five expressed the Le^a antigen and 11 the Le^b antigen. The intensity of staining with anti- Le^a , anti-sialyl Le^a , and anti- Le^b Mabs was weaker in OCP than in controls. Sialyl Le^a epitope immunostaining was negative or very weak in the goblet cells of two Le^a and nine Le^b OCP patients. One Le^a and nine Le^b patients did not express the Le^a epitope in contrast with normal conjunctiva (according to the well known slight cross reaction of Le^b and Le^a —see above in “Monoclonal antibodies”).

Epithelial cells

As in goblet cells, conjunctival epithelial cell immunoreactivity for sialyl Le^a epitopes was slightly weaker in Le^b OCP patients than in Le^b normal individuals (fig 2). In two patients, no immunostaining was seen with the four Mabs

Figure 2 Conjunctival sample from a Le^b patient ($Le(a-b+)$) with OCP. (A) Anti- Le^b Mab markedly stained the cytoplasm of the epithelial cells. (B) Anti-sialyl Le^a Mab did not stain the epithelial cells. Small arrows indicate the nuclei of the haematein counterstained epithelial cells. Goblet cells are absent (magnification $\times 500$).

indicating that they had a Le^c phenotype. Le^d was not expressed in OCP patients

Comparison of the Lewis and secretor phenotypes of OCP patients and normal French population

Serological tests were performed in 17 of 22 OCP patients, and as in normal individuals, the same Lewis phenotype was found in red blood cells as in the conjunctiva. Therefore, immunohistological processing of the conjunctiva can be used for phenotypic studies comparing normal and cicatricial pemphigoid populations. There was a statistically significant difference ($p = 0.047$) between both populations with respect to the non-secretor phenotype (Le^a and Le^c), which was found in 41% (nine out of 22 patients) and 20% (17 out of 89 normal subjects) in the OCP group and the normal French population,¹⁸ respectively (table 2).

DISCUSSION

According to the results of previous conventional histochemical studies, the mucin produced by goblet cells in OCP does not seem to differ from the mucin secreted by normal conjunctiva. Wells *et al* showed that goblet cells of OCP patients and normal individuals were stained with PNA (peanut agglutinin), HPA (*Helix ponatia* agglutinin), WGA (wheat germ agglutinin), and sWGA (succinylated wheat germ agglutinin).¹⁷ The binding of native WGA to the superficial conjunctival cells indicated the presence of N-acetyl-glucosamine and/or sialic acid and its residues. Results of sodium dodecyl sulfate polyacrylamide gel electrophoresis studies have also shown that conjunctival mucus electrophoretic motility was similar in OCP, Stevens-Johnson syndrome, rosacea blepharoconjunctivitis, and normal individuals.¹⁶

As in previous studies, we showed that conjunctival goblet cells were scarce or absent in OCP patients.^{24–26} However, changes observed during OCP seem to be both quantitative and qualitative regarding mucin characteristics. The changes involved the carbohydrate structure of the oligosaccharide chains, but not the peptidic core encoded by MUC5AC gene. It should be of great interest to study membrane associated mucins which constitute a very important mucous component involved in many ocular surface disease.²⁷ The immunoreactivity of blood group related antigens of goblet cells was reduced in OCP patients compared to normal individuals, suggesting a decreased activity of the fucosyl and sialyltransferases.²⁸ Our finding of a weak sialyl Le^a immunoreactivity in secretor patients suggests that sialylated glycoconjugates were less expressed. This may be partly the result of the competition between sialyltransferase and fucosyltransferase in secretor individuals. One hypothesis is that inflammation enhances the fixation of fucose rather than sialic acid. We showed a similar immunopathological pattern in pterygium—for example, a decreased sialyl Le^a immunostaining that may be related to a lower expression of ST3GalIII gene than in normal conjunctiva.^{28–30} Abnormal sialyltransferase activity observed during cell differentiation or maturation, particularly in tumours deserves to be investigated.³⁰ Decreased activity of glycosyl transferase could be assessed with direct assay of glycosyltransferase activity and/or measurement of mRNA levels in OCP patients.

We also demonstrated in our study that the percentage of individuals with non-secretor phenotype was higher in OCP patients than in the normal French population. The mechanisms by which oligosaccharide epitopes, and more particularly blood group related antigens, could be involved in the pathogenesis of OCP are unclear. Lewis, secretor, and ABO loci control the glycosyltransferase involved in the synthesis of the oligosaccharide chains. Their role has already been established in lung function, wheezing and asthma.³¹ It has been suggested that non-secretor patients could be more prone to develop mucous membrane diseases.²⁹ It has been hypothesised that oligosaccharide epitopes are necessary for the recognition of some micro-organisms. Blood group related antigens have been involved in the pathogenesis of *Helicobacter pylori* associated diseases, as Le^b patients may be more susceptible to develop gastric ulcer.^{32–33}

Six of the 22 OCP patients included in our study did not disclose the typical immunopathological features of the disease consisting of immune deposits at the conjunctival basement membrane. However, it has been shown that failure to demonstrate this deposition in a typical disease was possible, probably because of a lack of sensitivity of the technique.³⁴ The immunopathological proof is thereby not mandatory if the disease fulfils all diagnostic clinical criteria. In our study, all six OCP suspects had or later developed typical extraocular lesions of CP, and responded well to

systemic immunosuppressive therapy. Other systemic and ocular non-autoimmune fibrosing conditions were also easily ruled out.³⁴ Moreover, there were no change in the conjunctival staining between biopsy proved and the suspect OCP patients.

In conclusion, we characterised the conjunctiva of patients with OCP with respect to the peptidic MUC5AC and blood group related antigens of mucins. We observed some patterns of glycoconjugate epitopes but not of the peptidic core detected by anti-M1/MUC5AC MAb suggesting an abnormal glycosyltransferase expression. We also found an increase in the percentage of non-secretor phenotype in our patients. However, we are aware of the possible bias owing to the retrospective nature of the study as well as the lack of membrane associated mucin characterisation. Further studies including more patients are required to confirm these findings and to help us in a better understanding of the pathogenesis of autoimmune cicatrising conjunctivitis.
