Abnormal prion protein in the retina of the most commonly occurring subtype of sporadic Creutzfeldt-Jakob disease

M W Head, A H Peden, H M Yull, D L Ritchie, R E Bonshek, A B Tullo, J W Ironside

Background: Involvement of the eye has been reported in patients with variant Creutzfeldt-Jakob disease (vCJD), but there is disagreement on whether retinal involvement occurs in sporadic Creutzfeldt-Jakob disease (sCJD).

Methods: Western blotting, paraffin embedded tissue blotting, and immunohistochemistry were used to test whether the abnormal form of the prion protein (PrPSc) accumulates to detectable levels in the eye in a case of the most common subtype of sCJD (MM1).

Results: Low levels of PrPSc were detectable in the retina, localised to the plexiform layers of the central retina. PrPSc was not detectable in other ocular tissues.

Conclusions: The abnormal form of the prion protein is present in the retina in the most common sCJD subtype (MM1), albeit at levels lower than those found previously in vCJD and in sCJD of the VV2 subtype.

Creutzfeldt-Jakob disease (CJD) is a human prion disease that occurs in sporadic, acquired, and familial forms. The cause of sporadic CJD (sCJD) is not known with certainty, but the familial forms of CJD are all associated with mutations in the prion protein gene (PRNP). Acquired forms of the disease include variant CJD (vCJD), resulting from human infection with the bovine spongiform encephalopathy agent, and iatrogenic CJD. Iatrogenic CJD has been associated most recently with blood transfusion but also historically with human cadaveric tissue transplantation. Although there is no epidemiological evidence for other forms of ophthalmic surgery having resulted in CJD transmission between patients, it cannot be ruled out.

Determining the extent of tissue involvement in the different forms of CJD is an important component of a rational assessment of the risk of iatrogenic CJD transmission associated with a given medical procedure. Infectivity can be assessed directly by animal transmission studies and the eye has previously been shown to harbour infectivity, although the responsible ocular component was not identified. An alternative approach is to use the disease associated abnormal form of the prion protein, PrPSc, as a marker of infectivity. In general, the tissue distribution of PrPSc in vCJD is very much wider than in sCJD, including the lympho-vascular system in addition to the central nervous system. The two papers that have reported on ocular tissues in vCJD were in agreement that PrPSc is present at readily detectable levels in neurosensory retina and in the optic nerve, but is undetectable in the cornea, lens, vitreous body, and sclera. However, these same studies did not concur over sCJD. Even with a highly sensitive Western blotting technique, Wadsworth and colleagues were unable to detect PrPSc in any ocular component of the eye from the case of sCJD available to them. We found, however, that PrPSc was detectable at levels similar to those found in the brain and distributed uniformly throughout the plexiform layers in the retina from the eye of a patient with sCJD. One possible explanation for this discrepancy is the known diversity of clinical and pathological phenotype in sCJD. This depends partly on the PrPSc type present (either type 1 or type 2) and on the methionine/valine polymorphism at codon 129 of the PRNP gene. The eye which we previously examined was from a patient who had type 2 PrPSc in the brain and was homozygous for valine at codon 129 of PRNP (that is, VV2). We have recently had the opportunity to readdress this issue by examining both fixed and frozen eye tissues from a 67 year old man referred to the National CJD Surveillance Unit with suspected CJD. Autopsy examination confirmed the diagnosis of sCJD, and the biochemical and genetic tests identified this to be of the most commonly occurring MM1 subtype. Consent was given for tissue retention and research use.

MATERIALS AND METHODS
Western blot analysis for PrPSc was carried out using the method described previously. Briefly, frozen tissues were homogenised in a non-denaturing detergent buffer at 10% tissue weight/volume of buffer. The cleared homogenate was digested with 50 μg/ml proteinase K (Merck Biosciences, Beeston, UK) at 37°C for 1 hour. Protease resistant PrPSc was analysed by Western blotting using 10% NuPage bis-tris gels, horseradish peroxidase conjugated anti-mouse secondary antibody, and the signal captured by enhanced chemiluminescence (ECL+ using x ray film (all from Amersham Biosciences, Bucks, UK). Western blots were probed with the monoclonal antibody 3F4 (Dako, High Wycombe, UK), horseradish peroxidase conjugated anti-mouse secondary antibody, and the signal captured by enhanced chemiluminescence (ECL+) using x ray film (all from Amersham Biosciences, Bucks, UK). In some experiments a modified tissue dispersion step employing a FastPrep tissue homogeniser (Qiogene, Cambridge, UK) was used in combination with a preparatory step that employs sodium phosphotungstic acid precipitation of PrPSc from a larger volume of tissue homogenate. Paraffin embedded tissue blotting using the monoclonal antibody 3F4 was performed to localise PrPSc in sections of the fixed eye. Finer localisation was achieved using immunohistochemistry with the 12F10 monoclonal antibody (IDS Ltd, Tyne and Wear, UK).

RESULTS
Western blot analysis using the standard method showed that type 1 PrPSc was abundant in the brain (frontal cortex) from this case of sCJD. In contrast, PrPSc was undetectable in a sample of retina (fig 1A). We then re-sampled the ocular tissues and prepared tissue homogenates using a modified tissue dispersion step employing a FastPrep tissue homogeniser (Qiogene, Cambridge, UK).

Abbreviations: sCJD, sporadic Creutzfeldt-Jakob disease; vCJD, variant Creutzfeldt-Jakob disease
homogeniser. Standard Western blot analysis again failed to detect PrPSc in the retina even on maximal exposure (fig 1B). The remaining FastPrep tissue extracts (500 μl) were then used in a sodium phosphotungstic acid precipitation assay. Using this method to selectively precipitate PrPSc before Western blot analysis, a positive signal was seen in the retina sample (fig 1C). No PrPSc was detectable in the cornea, lens, iris, vitreous body, sclera, or extraocular muscle in the standard assay or in the phosphotungstic acid precipitation experiments. A faint signal was obtained from the sample of optic nerve (data not shown).

The paraffin embedded tissue blot method was then used to assess the regional distribution of PrPSc in the retina and cornea (fig 1A). Analysis of a second sample of retina from the patient (lane 3), alongside a standard sample of variant CJD brain before (lane 1) and after (lane 2) treatment with proteinase K. (C) 500 μl of a 10% (w/v) retinal extract from this patient is shown after precipitation with phosphotungstic acid (lane 3) and the position of the positive signal is marked (⁎). Lanes 1 and 2 show 1 μl of a 10% (w/v) standard homogenate of variant CJD brain before (lane 1) and after (lane 2) digestion with proteinase K. All blots were probed with the antibody 3F4.

DISCUSSION

The results presented here go some way to resolving the discrepancy between the two published studies of ocular involvement in cases of sCJD. Prominent and uniform retinal involvement appears to be a characteristic feature of vCJD and was also evident in the one case of sCJD of the VV2 subtype examined. In contrast, PrPSc is much less readily detectable in the retina in the more common MM1 subtype of sCJD. Although undetectable by biochemical assays in the MM1 sCJD case analysed by Wadsworth and colleagues, PrPSc is detectable in the retina of the MM1 sCJD case presented here, both by biochemical and histological based assays, but its level is very much lower and its distribution is perhaps less uniform. The amount of PrPSc detected in the retina by phosphotungstate precipitation assay was between one hundredth and one thousandth of the level found in the vCJD positive control brain sample.

Sporadic CJD is thought to originate from a chance conversion of the normal form of the prion protein to the abnormal form (PrPSc) in the brain in affected individuals. The presence of PrPSc outside the brain has been interpreted as centrifugal spread from the brain to the periphery, in the case of the eye, via the optic nerve with subsequent accumulation being a characteristic of regions of high synaptic density such as the plexiform layers of the retina.
PrPSc positivity is known from animal studies to progress at a slow but defined rate (~1 mm/day) along neural pathways. It follows that ocular involvement could be considered to be a function of the presence of PrPSc in the relevant region of the brain, the time during which it can spread via the optic nerve to the retina, and the opportunity that it has to accumulate in the synaptic layers. The mean duration of illness in sCJD is shorter than that of vCJD, and this is particularly true of the duration of the MM1 subtype of sCJD which progresses very slowly but defined rate (~1 mm/day) along neural pathways. The cases of sCJD that we have reported are typical of their subtypes. The duration of the illness in the VV2 sCJD case we reported previously was 9 months, whereas the MM1 patient reported here had a duration of illness of only 1 month. We would predict that any larger study of ocular involvement in CJD might find a correlation between the level and extent of PrPSc accumulation in the retina and disease duration. A similar argument has recently been advanced to explain why some (but not all) cases of sCJD have detectable PrPSc in spleen and skeletal muscle.

Irrespective of whether this general explanation is found to be correct, this study clearly indicates that the retina should be considered a potential source of transmissible infection when ophthalmic surgery is performed on any patient suffering from neurological symptoms consistent with a diagnosis of CJD. The results also underscore the importance of localisation studies in addition to sensitive biochemical tests when analysing tissues that might be heterogeneous in their accumulation of PrPSc.

ACKNOWLEDGEMENTS

The authors thank the patients’ relatives for their consent to retain and perform these studies on tissue specimens.
