Actions of bevacizumab and ranibizumab on microvascular retinal endothelial cells: similarities and differences

Heidrun L Deissler,1 Helmut Deissler,2 Gabriele E Lang1

ABSTRACT
Background Retinal endothelial cells are crucially involved in the genesis of diabetic retinopathy which is treated with vascular endothelial growth factor (VEGF) inhibitors. Of these, ranibizumab can completely restore VEGF-induced effects on immortalised bovine retinal endothelial cells (iBREC). In most experiments supporting diabetic retinopathy therapy with bevacizumab, only non-retinal EC or retinal pigment epithelial cells have been used. Also, bevacizumab but not ranibizumab can accumulate in retinal pigment epithelial cells.

Objective To investigate the effects of bevacizumab on VEGF-induced changes of iBREC properties and potential uptake and accumulation of both inhibitors.

Methods Uptake of VEGF inhibitors by iBREC with or without pretreatment with VEGF165 was visualised by immunofluorescence staining and western blot analyses. Measured transendothelial resistance (TER) of iBREC (±VEGF165) showed effects on permeability, indicated also by the western blot-determined tight junction protein claudin-1. The influence of bevacizumab on proliferation and migration of iBREC was studied in the presence and absence of VEGF165.

Results Bevacizumab strongly inhibited VEGF-stimulated and basal migration, but was less efficient than ranibizumab in inhibiting VEGF-induced proliferation or restoring the VEGF-induced decrease of TER and claudin-1. This ability was completely lost after storage of bevacizumab for 4 weeks at 4°C. Ranibizumab and bevacizumab were detectable in whole cell extracts after treatment for at least 1 h; bevacizumab accumulated during prolonged treatment. Ranibizumab was found in the membrane/organelle fraction, whereas bevacizumab was associated with the cytoskeleton.

Conclusion Both inhibitors had similar effects on retinal endothelial cells; however, some differences were recognised. Although barrier properties were not affected by internalised bevacizumab in vitro, potential adverse effects due to accumulation after repetitive intravitreal injections remain to be investigated.

INTRODUCTION
Vascular endothelial growth factor (VEGF) and its receptors are promising targets for treating diabetic retinopathy (DR), particularly diabetic macular oedema (DME), as elevated levels of VEGF have been found in the vitreous fluid and retinal vascularisation of patients.1–3 Accordingly, the VEGF-binding antibody fragment ranibizumab has recently been approved for DME therapy; the humanised VEGF-specific antibody bevacizumab is also used.4 5 The most important variant, VEGF165, not only elevates permeability of retinal endothelial cells (REC), likely leading to DME in vivo, but also stimulates proliferation and migration of REC to initiate neovascularisation.6–12 Several in vitro studies have confirmed that VEGF-stimulated proliferation of retinal or choroidal endothelial cells is inhibited by ranibizumab or bevacizumab.10 12 13 Increased permeability of immortalised bovine REC (iBREC) induced by long-term exposure to VEGF165, accompanied by loss of plasma membrane-localised tight junction (TJ) protein claudin-1, was completely restored by treatment with ranibizumab, even in the presence of other growth factors.9 14 Despite their similarity, deviating pharmacological activities of the VEGF inhibitors may result from differences in accumulation in relevant cell types, which has been shown for retinal pigment epithelial (RPE) cells: only bevacizumab was transported through the plasma membrane and its intracellular amounts increased over several days.15 Sufficiently accumulated bevacizumab affected phagocytotic uptake of photoreceptor outer segments by RPE cells and also their barrier function.16 17 In contrast, ranibizumab only transiently impaired the barrier formed by these cells, and their phagocytotic uptake was not altered by exposure to this drug.16 17 These findings suggest that mechanisms of therapeutic activity of both VEGF inhibitors involving REC might also differ in relevant details. Therefore we used the established model cell line iBREC to investigate the efficiency of bevacizumab to restore VEGF-induced effects on proliferation, migration and barrier function. In addition, uptake of both VEGF inhibitors by iBREC and potential consequences were studied.

MATERIALS AND METHODS
Reagents, antibodies and media
Recombinant human VEGF165 was obtained from R&D Systems (Wiesbaden, Germany). Ranibizumab (Lucentis, 10 mg/ml), the Fab fragment of a humanised VEGF-binding antibody, was a gift from Novartis Pharma (Nuremberg, Germany).18 The anti-VEGF antibody bevacizumab (Avastin, 25 mg/ml) was purchased from Roche Pharma (Basel, Switzerland); aliquot parts were stored in inert plastic vessels at 4°C.19 Alternatively, bevacizumab was repackaged at the pharmacy of the University Hospital Ulm and provided in syringes which were stored at 4°C. Rabbit polyclonal antibodies binding to human claudin-1 (JAY8) or claudin-5 (Z43JK) and AlexaFluor 594-conjugated detection antibodies were from Invitrogen (Karlsruhe, Germany); goat polyclonal antibodies directed against canine VEGF (cross-reacting with bovine VEGF) were from R&D Systems.
Cultivation of iBREC and treatment with growth factors and inhibitors

Telomerase-immortalised microvascular endothelial cells from bovine retina (iBREC) were cultivated in endothelial cell growth medium (ECGM; Promocell, Heidelberg, Germany) supplemented with 0.4% endothelial cells growth supplement/H, 10 ng/ml epidermal growth factor and 105 nM hydrocortisone and 5% fetal calf serum (FCS) as described previously.14 20

Prior to experiments with confluent iBREC, the serum concentration of ECGM was reduced to 0.25% FCS for 24 h. After treatment with 100 ng/ml VEGF165 for 2 days, cells were incubated with medium containing 100 ng/ml VEGF165, and 100 µg/ml ranibizumab or 250 µg/ml bevacizumab, for at least 24 h before cell extracts were prepared.14 To study the effect of VEGF inhibitors on unstimulated cells, iBREC were kept in medium with 100 µg/ml ranibizumab or 250 µg/ml bevacizumab for periods from 50 min to 6 days.

Preparation of subcellular fractions and western blot analyses

Subcellular fractions were prepared with the ProteoExtract Subcellular Proteome Extraction Kit (Merck, Darmstadt, Germany) according to the manufacturer’s instructions; yielding proteins localised in the cytosol, in membranes/organelles, in the nucleus, and in components of the cytoskeleton. Cytosolic, membrane and nuclear fractions were cleared by additional centrifugation (10 000g, 4°C) for 10 min.

Western blot analyses of whole cell extracts or subcellular fractions were performed as described.11 14 Analyses of ranibizumab and bevacizumab were based on immunoreactivity of polyclonal antibodies (coupled to horseradish peroxidise) with human IgG (1:20000, Invitrogen). For semi-quantitative assessment, specific chemiluminescence signals were compared to those of standard samples used in the range 0.5–50 ng.

Immunofluorescence staining

Confluent monolayers of iBREC on fibronectin-coated two-chamber slides (Nunc, Wiesbaden, Germany) were treated with effectors as described above and antigens were visualised by immunofluorescence staining.10 Internalised ranibizumab or bevacizumab were stained by incubation with AlexaFluor594-coupled polyclonal antibodies (1:10000) against human IgG for 90 min after blocking with 10% FCS/PBS for 50 min. To determine the limit of detection, diluted samples of the inhibitors were spotted on an appropriate membrane and processed alike.

Transendothelial electrical resistance of cell layers

To assess paracellular permeability of iBREC, transendothelial electrical resistance (TER) was measured as described previously.11 14 Normalised TER values were calculated in relation to the TER measured in low serum medium immediately before the medium was replaced by fresh medium containing effectors.

Cell migration and proliferation assays

Cell migration assays were performed in a modified Boyden chamber; enzymatic conversion of WST-1 (Roche), indicative of proliferating cells, was measured 24 h after addition of effectors to iBREC as described previously.10 Values were normalised to those obtained with control cells not treated with effectors.

General considerations and statistical analyses

In all experiments, control cells were processed identically in medium only lacking the effector(s) under investigation. All experiments were repeated at least three times; in each experiment, data were generated from multiple replicates. The Mann–Whitney U test was used to compare sets of experimental data; differences resulting in p values below 0.05 were considered significant. Results are presented either as conventional box-whiskers diagrams showing means and percentiles (75%, 25%) or by providing means and corresponding standard deviations.

RESULTS

Bevacizumab inhibits VEGF165-induced proliferation and migration

Our previous studies showed that stimulation of proliferation and migration of iBREC with VEGF165 is completely suppressed by 100 µg/ml ranibizumab.10 To compare the inhibitory effect of the related drug bevacizumab, serum-starved iBREC were exposed to VEGF165 and bevacizumab for 24 h before conversion of WST-1 was determined as a measure of cell proliferation. Only partial inhibition of VEGF-stimulated proliferation by bevacizumab was observed under these conditions (figure 1A). VEGF-stimulated migration of iBREC towards fibronectin in a modified Boyden chamber was not only strongly inhibited by bevacizumab, but was even driven below basal migration rates (figure 1B). The effect of bevacizumab on proliferation or migration of iBREC was not dependent on time and conditions of its storage prior to the experiments.

Bevacizumab restores a VEGF165-impaired iBREC barrier

In accordance with previous investigations, treatment of iBREC with VEGF165 significantly decreased the TER within 2 days (figure 2A).14 After addition of bevacizumab to the VEGF-pretreated cells, TER increased within 1 day but reached normal values only during prolonged exposure (figure 2A), whereas almost complete reversion was achieved after 1 day with ranibizumab. Like ranibizumab, bevacizumab completely reinstated the VEGF-induced loss of claudin-1 (figure 2B,C). This effect of potential therapeutic relevance on TJs was entirely lost after

Figure 1  Vascular endothelial growth factor (VEGF165)-stimulated proliferation and migration of immortalised bovine retinal endothelial cells (iBREC) is inhibited by bevacizumab. (A) Serum-starved iBREC were incubated with VEGF165 in the presence or absence of bevacizumab and their proliferation was measured after 24 h. (B) iBREC migration towards fibronectin was measured in a modified Boyden-chamber. VEGF165-stimulated migration was inhibited by bevacizumab below the level of basal migration.
storage of the repackaged solutions of bevacizumab at 4°C for more than 4 weeks (figure 2B). In contrast, ranibizumab effectively reverted the loss of claudin-1 when stored under the same conditions (figure 2C). Whereas the capacity of bevacizumab to revert VEGF-induced vanishing of claudin-1 was dependent on its storage history, prevention of this process was not affected, even after prolonged storage (figure 2D). Western blot analyses confirmed that neither protein fragmentation nor formation of aggregates occurred during long-term storage of bevacizumab or ranibizumab solutions.

Uptake of bevacizumab and ranibizumab by iBREC

First we confirmed that the Fab fragment ranibizumab and the whole antibody bevacizumab were both bound by polyclonal antibodies against human IgG, and that the detection limits (25 ng for immunofluorescence staining, 0.5 ng for western blot analyses) were low enough. To monitor uptake by iBREC, their confluent monolayers were incubated with bevacizumab or ranibizumab for various periods from several hours to 6 days. Internalised drugs were visualised by immunofluorescence staining or determined in cell lysates (figures 3 and 4). After treatment for 50 min, a diffuse bevacizumab-specific staining was observed, which was focused around the nucleus in cells that had been exposed longer to this antibody (figure 3, right column). Staining intensity and pattern were not affected by pretreatment with VEGF 165 for 1 day. In contrast to the observed uptake of bevacizumab, considerable amounts of ranibizumab were not detected by immunofluorescence staining in iBREC treated with this antibody fragment (figure 3, middle column). These results were confirmed by western blot analyses of whole cell extracts of iBREC treated with the VEGF inhibitors: bevacizumab was detectable after 1 h and accumulated during further incubation until day 6 (figure 4A). In contrast, less ranibizumab was taken up slower by iBREC and, despite prolonged incubation with the antibody fragment, the amount of internalised ranibizumab remained constant (figure 4B). Most of the bevacizumab absorbed by iBREC was found associated with the cytoskeleton and a smaller part in the subcellular fraction consisting of membranes and organelles (figures 3 and 4C), whereas ranibizumab was present in the membrane/organelle fraction but did not co-occur with cytoskeleton proteins (figure 4D). The different subcellular localisations of ranibizumab and bevacizumab were not affected by extended exposure or pretreatment with VEGF 165. In these experiments, VEGF was mainly detected in the membrane/organelle fraction in the absence or presence of VEGF inhibitors.

Effects of bevacizumab and ranibizumab on barrier, migration and proliferation of unstimulated iBREC

Destabilisation of the cell barrier, as reported for bevacizumab-treated RPE cells, was not observed when TER of iBREC was monitored during incubation with ranibizumab or bevacizumab for up to 6 days (figure 5A).17 Constant localisation of the tight-junction proteins claudin-1 and claudin-5 in the plasma

membrane was also indicative of a strong and stable barrier (figure 5B,C).

Migration of iBREC towards fibronectin was not altered in the presence of 60 µg/ml ranibizumab as shown by normalised migration rates of 104±34% versus 100±31% (control). In contrast, 150 µg/ml bevacizumab strongly and significantly reduced basal migration rates of iBREC (normalised values of 43±27%, p<0.001 for comparisons with control and ranibizumab-treated cells), indicating VEGF-independent effects of bevacizumab. Basal proliferation of iBREC (normalised rates of 100±12%) was not significantly affected by ranibizumab (104±12%) or bevacizumab (94±18%).

**DISCUSSION**

The humanised VEGF-binding antibody bevacizumab is widely used off-label to treat DME. Although REC are considered the most important target cells of VEGF in the development and progression of this disease, in vitro experiments performed to understand the mechanisms of the therapeutic effects of bevacizumab have been focused almost exclusively on non-retinal EC or RPE cells. In this investigation we used iBREC, a retinal cell line with the distinct advantage over primary ECs that contaminating cells of other types cannot be present in the cultures. Studies with iBREC ideally complement investigations based on rodent models of diabetes and may even be more relevant to clinical applications of drugs under investigation, because of the higher similarity of bovine proteins to their human counterparts. In our previous studies based on the iBREC model, we showed that ranibizumab, in addition to efficient inhibition of VEGF-stimulated proliferation and migration, can completely restore the VEGF-induced impairment of the endothelial barrier; this provided a rationale for using this antibody fragment in DME therapy. Stimulation of iBREC was carried out in these experiments, with concentrations of VEGF similar to those measured in the vitreous fluid of DR patients; concentrations of ranibizumab and bevacizumab reflected values found to be achievable by standard therapies with these drugs. We confirmed that bevacizumab inhibits VEGF-induced proliferation but is less efficient than ranibizumab; this was also observed in experiments with human REC and could be a consequence of its much lower affinity to VEGF. Likewise, the ability of bevacizumab to re-establish an intact iBREC barrier that had been deranged by VEGF was lower than that of ranibizumab. Despite being observed in vitro, this difference might be seen as a challenge to the assumption that both drugs are equivalent in the treatment of DR. Also of potential relevance for its clinical application is the surprising finding that bevacizumab repackaged in syringes and stored at 4°C for more

**Figure 3** Visualisation of bevacizumab internalised by immortalised bovine retinal endothelial cells (iBREC). iBREC were treated with bevacizumab (right column) or ranibizumab (middle column) after indicated times of incubation, inhibitors were visualised by immunofluorescence staining with antibodies against human IgG. Staining of ranibizumab-treated cells (middle column) was similar to the faint unspecific signals observed in control cells kept in standard medium (left column). Incubation with bevacizumab resulted in strong intracellular staining of iBREC.

**Figure 4** Semi-quantitative assessment of bevacizumab and ranibizumab in subcellular fractions of immortalised bovine retinal endothelial cells (iBREC). (A,B) iBREC were treated for 1 h to 6 days with 250 µg/ml bevacizumab (A) or 100 µg/ml ranibizumab (B) and whole cell extracts of 10⁵ cells (A) or 3×10⁴ cells (B) were subjected to western blot analyses. Defined amounts of both inhibitors were loaded for semi-quantitative assessment. The band specific for ranibizumab was most intense after treatment for 1 day. During prolonged exposure, the intracellular amount of bevacizumab but not that of ranibizumab increased. (C,D) iBREC were treated for 1 day with bevacizumab (C) or ranibizumab (D) in the absence or presence of vascular endothelial growth factor (VEGF₁₆₅); subcellular fractions of 2×10⁴ cells (C) or 5×10⁴ cells (D) were analysed. Defined amounts of both inhibitors were loaded for semi-quantitative assessment. Ranibizumab was detected in the membrane/organelle fraction. In contrast, higher amounts of bevacizumab were mainly found in the fraction of cytoskeleton proteins. Localisation was not affected by pretreatment with VEGF₁₆₅.
lower amounts of an inhibitor, and it is therefore less sensitive to
regulatory consequences as suggested by the finding that phagocy-
totic uptake of photoreceptor outer segments by porcine RPE
cells is inhibited after long-term exposure to bevacizumab, an
inhibitor of VEGF receptor 2 than for those restoring VEGF-decreased claudin-1. This suggests that elimination of VEGF from the extracellular space may not be sufficient to reverse its long-term effects on ECs and that additional mechanisms contribute to the therapeutic effects of drugs like ranibizumab and bevacizumab. Potential second targets may be secreted factors like VEGF or cell surface molecules on ECs, but internalised drugs may also affect intracellular processes.

After treatment for 1 day, about 40 000 molecules of ranibi-
zumab were calculated to be present inside iBREC. Association of ranibizumab with the organelle/membrane fraction is in accordance with the speculation that this substance is internalised by endocytosis to be degraded. Then the constant intracellular amounts of ranibizumab observed during prolonged exposure can be considered a steady state in which uptake and degradation of the protein are balanced. In contrast, a higher amount (~100 000 molecules per cell) of bevacizumab measured after one day in iBREC further increased when the cells were kept in medium containing the antibody. Most of the accumu-
lated bevacizumab was found associated with the cytoskeleton, which might be the reason for the surprisingly observed inhibition of basal migration of iBREC. Because serum-free medium was used in this assay, this inhibitory effect could not be caused by targeting residual amounts of VEGF. The part of internalised bevacizumab found in the organelle/membrane fraction could be degraded like ranibizumab, but this process seems to be not fast enough to avoid an increase of intracellular amounts. Treatment of iBREC with VEGF 
findings that phagocytotic uptake of photoreceptor outer segments by porcine RPE cells is inhibited after long-term exposure to bevacizumab, an
effect not observed with ranibizumab. Considering the typical ages of the DME-patients and duration of treatment, these results strongly suggest further investigations to exclude any harmful long-term consequences for retinal cells due to accumulation of bevacizumab after repetitive injections.
